Human immunodeficiency virus (HIV) can be passed from mother to child via breastfeeding. In the United States, both the CDC[16] and the AAP[17] discourage mothers living with HIV from breastfeeding or using their milk for their infants, regardless of antiretroviral therapy or maternal viral load. Conversely, WHO supports breastfeeding by HIV-infected mothers in many developing countries due to health issues related to the availability of clean water and affordable infant formula.[18] These contrasting recommendations may result in confusion for mothers living with HIV in the United States who wish to breastfeed and their healthcare providers.[19] Mothers living with HIV who elect to breastfeed must be counselled on the importance of adherence to their HIV treatment regimen and potential HIV prophylaxis for their infant. Mothers with untreated tuberculosis should pump until treated for at least 2 weeks and no longer infectious. Mothers with an active herpes simplex virus (HSV) infection on the breast, varicella infection presenting within 5 days before birth or 2 days after, or H1N1 influenza or SARS-CoV-2 must be isolated from their infants, but the infant can receive their mother's expressed milk.[8,15]

Donor Human Milk

For mothers unable to breastfeed or to supply sufficient milk for their infants, donor human milk is an acceptable alternative, especially for extremely premature infants. Donor human milk is available through donor human milk banks and used in many neonatal intensive care units (ICU). The Human Milk Banking Association of North American (HMBANA; www.hmbana.org) sets policies for donor human milk (not the US Food and Drug Administration [FDA]) and accredits 31 donor milk banks in the United States (28) and Canada (3) with others in development. Each milk bank also sets its own standards that may be more stringent than the HMBANA standards.[20]

Donor human milk is pooled from multiple, unpaid, extensively screened (health screening, blood serology testing) donors, which limits the risk of transmission of viral and bacterial infections. Holder pasteurization is used to eliminate viral and bacterial pathogens from the donated human milk and also decreases the overall number of neutrophils, stem cells, and IgA (50% loss) in the milk. However, it still supplies more of these beneficial components than if the infant were to receive formula. Donor human milk may contain cow milk or soy protein if the donor's diet contained dairy or soy, thus allergy symptoms can occur. Insurance coverage for donor human milk varies from state to state; however, the coverage rate for extremely premature and other high-risk infants is good. Access to donor milk for all who could benefit from its use is limited by supply, cost, and distribution issues.[21]

Macronutrients in Human Milk

Human milk is a complex mixture that is approximately 87% water, 3.8% fat, 1% protein, and 7% lactose. Fat and lactose provide 50% and 40% of the total energy, respectively.[22] Human milk contains enough water (87%) to meet an infant's fluid needs without additional fluid intake. The first fluid secreted by the breast after delivery is an intense yellow fluid (high in carotenoids) called *colostrum*. Although secreted in small amounts, it contains secretory immunoglobulin A (IgA), lactoferrin, leucocytes, and epidermal growth factor. By 2 to 4 weeks, human milk is considered *mature* and provides approximately 18 to 22 kcal/oz (2.5-3.1 kJ/mL) depending on the fat content.[23] Typically, an average of 20 kcal/oz (2.8 kJ/mL) is used for estimating an infant's caloric intake. The composition of human milk is dynamic—changing even from feeding to feeding. Lactose is the primary sugar in human milk. Human milk also contains prebiotic oligosaccharides (30 or more) with fructooligosaccharides (FOS) and galactooligosaccharides (GOS) being most abundant. These oligosaccharides mimic bacterial antigen receptors and prevent bacterial attachment to the intestinal wall.[22]

The principal proteins in human milk are casein (homologous to bovine beta-casein) and whey. Casein curdles in the stomach, but whey remains a liquid and is easier to digest. Whey proteins are broken down rapidly to free amino acids. The whey:casein ratio varies from 70:30 to 80:20 in early lactation and is 50:50 in late lactation.[22] The main whey proteins are alpha-lactalbumin, lactoferrin, and secretory IgA, but there are many others. These proteins also have non-nutritive functions, particularly in immune function.

Fat in human milk is ~95% triglycerides but varies with maternal diet. Palmitic acid (23%) and oleic acid (36%) are the predominant fatty acids. Fat generally provides ~50% of the energy provided. The two essential fatty acids, linoleic acid (18:2n-6; arachidonic acid [ARA] precursor) and alpha-linolenic acid (18:3n-3; eicosapentanoic acid [EPA] and docosahexaenoic acid [DHA] precursor), are essential for central nervous system development. Human milk also contains the long-chain polyunsaturated fatty acids (LCPUFA), DHA (22:6n-3) and ARA (20:4n-6), which are the most abundant LCPUFA in the brain. DHA and ARA constitute 12% to 15% of the fatty acids in the cerebral cortex and brain stem gray matter. Retinal tissue also has a high concentration of DHA in both rod and cone outer segments and is essential for usual function.[24] After birth, large amounts of these LCPUFA are required for the regulation of growth, inflammatory response, and immune function and the development of vision, cognitive (learning, memory, behavior), and motor system function.[22] LCPUFA intake appears to be particularly important for the developing premature brain because large amounts accumulate in the fetus via the placenta during the last trimester.[22] The concentrations of DHA and ARA in human milk vary but intake is about 60 mg/day. In human milk, the DHA concentration depends on maternal fish intake, but ARA is independent of dietary intake.[24]

Human Milk Fortifiers

Human milk at any stage of lactation cannot fully supply the nutrient needs of premature infants, especially those born earlier than 34 weeks gestation. Human milk fortifiers (HMF) were developed to allow fortification of an aliquot of human milk to increase nutrient delivery while continuing to provide human milk to premature infants. HMF is available in both liquid and powder preparations (Table e21-3). The liquid or powder is generally mixed with human milk in a ratio of 1 packet to 25 mL to yield a concentration of 24 kcal/oz (3.4 kJ/mL) or 1 packet to 50 mL for a 22 kcal/oz (3.1 kJ/mL) concentration. In addition to increasing energy delivery, these products also increase the delivery of protein, calcium, phosphorus, zinc, and other nutrients. Although some high-risk infants may still require HMF at discharge, most infants are not discharged on HMF due to cost and availability. HMF can be obtained for infants that meet qualifications through the US Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). Human milk may also be fortified with a premature infant formula, a post-discharge premature infant formula, or a standard or specialty term infant formula depending on the infant's age, needs, and GI health. If a post-discharge premature infant formula is used for fortification, 1 teaspoonful powder is added to 90 mL of human milk to yield a concentration of 24 kcal/oz (3.4 kJ/mL). While quite common, this practice has been labeled *The Sprinkles Dilemma* because it results in uneven enrichment of nutrients and may not meet optimal nutrition intakes.[25] Table e21-4 provides examples of methods used to fortify human milk.

INFANT FORMULAS

② A commercial infant formula is a nutritionally complete substitute when human milk is not available. Infant formula composition is mandated by an amendment to the Federal Food, Drug, and Cosmetic Act, the Infant Formula Act of 1980 (amended 1986). These standards and other information can be found on the FDA website.[26] Regulations specify a minimum allowable amount of 29 ingredients and a maximum amount for nine ingredients, and manufacturers are required to test their products and report periodically to the FDA. Formulas exempted from these standards are labeled for use in infants with inborn errors of metabolism, low birth weight, or unusual medical or dietary problems, require a prescription for use, and cannot be sold retail.[26] Store-brand formulas are often more affordable, and caregivers can be assured that they will provide complete infant nutrition. Formulas that have been imported from outside the United States or purchased via the internet may not meet these FDA regulations and may cause harm.

The first commercial infant formula was introduced in the United States in 1919. In 2021, the $2.1 billion US infant formula market represented a decrease of 2.6% in annualized market size growth from 2016 to 2021.[27] The global infant formula market in 2018 was $24 billion with estimates of $45 billion by 2025.[28] Infant formulas are marketed in several forms: ready-to-feed, powder for reconstitution, and concentrated liquids that need to be diluted with water. The major infant formula manufacturers (Table e21-5) continuously modify their products to mimic human milk composition more closely and to improve nutrient delivery to infants with a variety of medical conditions. The manufacturer's website will likely have the most up-to-date information on a product. Formula choice depends on many factors including age, GI function, previous tolerance or intolerance to ingredients, nutritional requirements, and the presence of various diseases or conditions.

WIC Program

Parents who cannot afford to purchase enough formula may either inappropriately dilute the formula or limit the infant's intake to make the formula last longer. These practices can lead to electrolyte abnormalities (hyponatremia) and growth faltering. The federally funded WIC program began in 1974 serving about 88,000 infants with a budget of $10.4M. The WIC program is now the single largest purchaser of infant formula in the United States and serves more than 50% of all infants. In 2020, the WIC program served ~6.2 million participants (1.7M infants, 3.5M children, and 1.6M pregnant/lactating women) with a total budget of $4.9 billion.[29] State agencies are required by law to have competitively bid WIC formula rebate contracts with manufacturers. States agree to provide one brand of formula in return for substantial discounts (rebates); thus, the WIC provided brand varies from state to state. In 2017, these rebate generated savings ($1.74 billion) allowed WIC agencies to serve an additional 1.55 million participants each month (21.25% of the estimated average monthly caseload).[30] Many infants and children eligible for WIC cannot participate due to insufficient WIC resources. Other factors, such as parental/caregiver education, may also limit participation in the WIC program.

Macronutrients in Infant Formulas

Infant formulas generally provide 20 to 24 kcal/oz (2.8-3.4 kJ/mL)(term) or 20 to 30 kcal/oz (2.8-4.2 kJ/mL)(preterm) and differ primarily in their macronutrient (carbohydrate, protein, fat) composition. These composition differences are the primary basis for selecting a product for a given infant. Table e21-6 provides a classification for available infant formulas with examples of each type.

TABLE e21-6

Formulas for Term or Near-Term Infants[a] (Examples, Not a Complete List)

Formula Type	Indications	Products	Comments
Cow milk-based	Normal functioning GI tract; no food allergies	Enfamil® Enspire™, Enfamil® NeuroPro™ Infant, Enfamil® PREMIUM™ A2, Enfamil® Reguline®, Enfamil® Infant, Enfamil® 24, Similac® Advance®, Similac® Advance® 20, Similac Pro-Advance® 20, Similac® for Supplementation (non-GMO),[b] Pure Bliss™ by Similac® (non-GMO),[b] Gerber® Good Start® A2, Nestle NAN 1 Pro, *Store Brand* Infant, *Store Brand* Advantage®, Kirkland Signature™ Procare®	Most commonly used; DHA and ARA added
Cow milk-based, organic	Normal functioning GI tract; no food allergies; caregiver prefers organic	Earth's Best Organic, Similac® Organic, Similac® Organic with A2 Milk, Baby's Only LactoRelief, Baby's Only Organic DHA&ARA, Plum Organics Organic, Gerber® Natura Stage 1 Organic	
Cow milk-based, kosher	Kosher diet preferred	Similac® Advance® Lamehadrin Infant Formula	BADATZ-certified
Partially hydrolyzed cow milk-based	Normal functioning GI tract; colic	Gerber® Good Start® GentlePro, Gerber® Good Start® SoothePro, Similac Pro-Total Comfort® 20, Similac Total Comfort® 20, Enfamil NeuroPro™ Gentlease®, Enfamil Gentlease®, Enfamil Enspire™ Gentlease®, *Store Brand* Tender®, *Store Brand* Gentle®, *Store Brand* Complete® Comfort	Whey protein; possibly easier to digest
Lactose-free	Normal functioning GI tract; symptoms of lactose sensitivity; galactosemia	Similac Pro-Sensitive® 20, Similac Sensitive® 20, Similac Pro-Total Comfort® 20, Similac Total Comfort® 20, *Store Brand* Sensitivity®	~0.1 g lactose per 100 kcal
Lactose-reduced	Normal functioning GI tract; symptoms of lactose intolerance	Enfamil NeuroPro™ Gentlease®, Enfamil Gentlease®, Enfamil Enspire™ Gentlease®, Enfamil NeuroPro™ Sensitive, *Store Brand* Complete® Comfort, Similac® For Spit-up, Similac® For Spit-up (non-GMO)[b]	
Cow-milk based, added rice starch	Gastroesophageal reflux; feeding intolerance	Enfamil A.R.™, Similac® For Spit-up, Similac® For Spit-up (non-GMO),[b] *Store Brand* Added Rice Starch	Requires gastric acid to thicken in the

			stomach
Soy protein-based	Lactose intolerance; galactosemia; vegetarian	Enfamil® ProSobee®, Gerber® Good Start® Soy, Similac® Soy Isomil® 20, *Store Brand* Soy	
Extensively hydrolyzed protein (semi-elemental; hypoallergenic)	Lactose intolerance; cow milk or soy protein allergy; malabsorption; short bowel syndrome	Nutramigen® (Liquids), Gerber® Good Start® Extensive HA®, Similac® Alimentum®, Pregestimil®, Nutramigen® with Enflora™ LGG®, *Store Brand* Hypoallergenic	Lactose-free; some fat as MCT
Amino acid-based (elemental; hypoallergenic)	Cow milk or soy protein allergy; severe food allergies; short bowel syndrome; malabsorption	Alfamino® Infant, Elecare® Infant, Neocate®, Neocate® Infant, PurAmino™	Lactose-free; some fat as MCT

ARA, arachidonic acid; DHA, docosahexaenoic acid; GMO, genetically modified; MCT, medium chain triglycerides.

[a] May contain prebiotics, probiotics, or other non-nutrient additives.

[b] Made from fresh milk from grass-fed cows.

Data from Abbott Nutrition, Abbott Laboratories, Columbus, OH; Mead Johnson Nutrition, Glenview, IL; Nestlé SA, Vevey, Switzerland; Nutricia Advanced Medical Nutrition, Schiphol, the Netherlands; Perrigo, Allegan, MI.

Carbohydrates

There are several classes of dietary carbohydrates, including starch (glucose polymers) and disaccharides (sucrose, lactose), but only monosaccharides (glucose, fructose, galactose) can be absorbed. Digestion to monosaccharides depends on the intestinal brush border enzymes: sucrase, isomaltase, glucoamylase, and lactase. These enzymes are produced in response to a meal that contains carbohydrates, then degraded, so they must be resynthesized by the enterocytes before the next meal. All enzymes except lactase are synthesized in excess of the amount needed. Monosaccharides are transported across the enterocyte membrane. Glucose and galactose uptake is sodium-dependent, and fructose is absorbed via facilitated diffusion. Enzyme production and transport protein synthesis can be affected by genetic mutations resulting in carbohydrate maldigestion and malabsorption (eg, galactosemia, glycogen storage diseases).[31]

Carbohydrate sources in infant formulas vary and include lactose; corn syrup solids (glucose); maltodextrin; sucrose; and corn, tapioca, and potato starch. Cow milk-based formulas contain primarily lactose; corn syrup solids (glucose) may be added if the lactose has been removed or reduced. Formulas intended for infants with carbohydrate malabsorption or maldigestion contain maltodextrin; corn syrup solids (glucose); or modified corn, tapioca, or potato starch. Added sugars in infant formulas compared to human milk have been implicated in rapid weight gain and too rapid upward weight-for-age percentile crossing.[32]

Protein

Protein must be digested into small peptides or amino acids to be absorbed. Protein absorption begins with acid and pepsin in the stomach, then endo- and exopeptidases from the pancreas hydrolyze the protein in the duodenum and jejunum. There are many amino acid transporters in the enterocytes, and mutations can occur that alter their function. Peptides are absorbed through a sodium-dependent process by peptide transporter 1, which is also involved in drug absorption. There is significant transporter redundancy; some transporters have narrow substrate specificity for amino acids, while others have broader or overlapping substrate specificity for di- and tripeptides. A defect in one transporter usually does not result in the inability to absorb a specific amino acid or peptide.[33]

Protein sources in infant formulas include cow milk protein (casein and whey), soy protein, and casein and whey hydrolyzed to peptides and amino acids. Specialty infant formulas may contain hydrolyzed proteins that vary in the degree of hydrolysis from partial hydrolysis (peptide-based) to extensive hydrolysis (amino acid-based). Cow milk contains more than 30 proteins, but it is predominantly casein (82% casein), including α-casein, ß-casein, and κ-casein. Whey proteins include bovine immunoglobulin, lactoferrin, serum albumin, α-lactalbumin, and ß-lactoglobulin. Some cow milk-based formulas are altered to contain predominantly whey protein or are supplemented with whey to improve protein digestion. ß-lactoglobulin, α-lactalbumin, and casein are responsible for most cow milk allergies.[34]

Fat

Fat is an important calorie source for infants. Skimmed, nonfat cow milk is used to manufacture many infant formulas; thus, the fatty acids found in infant formulas are provided by the addition of coconut, corn, soy, sunflower, or safflower oil. Palm olein oil is no longer added as it decreases calcium absorption. The LCPUFA, ARA, and DHA, found in human milk are added to most infant formulas to mimic human milk. Infant formulas not supplemented with DHA and ARA provide minimal amounts. Addition of ARA and DHA (synthesized in a bioreactor) is supported by most nutrition experts, but addition to infant formulas is not mandated by regulatory authorities.[26] Most major baby formula companies have DHA- and ARA-supplemented versions of all their formulas. Although theoretically important, no cognitive benefit, as measured by academic performance, has been demonstrated with the addition of DHA and ARA.[35]

Medium chain triglycerides (MCT) are absorbed by simple diffusion which bypasses the need for lipase, bile (micelle formation), and transport via the lymphatic system. Additionally, unlike fatty acids, MCT transport into the mitochondria is carnitine independent. Infant formulas contain 0% to 87% of the fat as MCT depending on the intended patient population. An increased MCT supply is particularly important in patients with disturbances of fat digestion and absorption such as those with inadequate bile secretion, celiac disease, short bowel syndrome, inflammatory bowel disease, disturbed lymph flow, cystic fibrosis, some metabolic diseases, as well as in prematurely born neonates who have some degree of fat malabsorption. Because MCT are not a source of essential fatty acids, infants receiving a formula with high MCT content are at risk of developing essential fatty acid deficiency (EFAD).[36]

Formulas for Normal Healthy Infants

Term (or Near-Term) Infant Formulas

Many formulas are available for term infants (Table e21-6), and new or modified formulas are marketed each year as manufacturers continually strive to make their formulas as close to human milk as possible. The initial formula choice for a healthy term or near-term infant is generally made by the hospital, parent/caregiver, or WIC. The choice is based primarily on cost but may be based on other considerations. Caregivers often change their infant's formula without consulting a healthcare provider when there are concerns such as straining with stooling, constipation, excessive gas, frequent spitting up or vomiting, or colic. Parents should be educated that bloody stools and persistent or bilious vomiting may be signs of serious conditions, and medical attention should be sought rather than just changing the formula. Cow milk protein allergy occurs in 2% to 7.5% of infants and can present as wheezing, skin rash, diarrhea, or bloody stools; symptoms which require medical attention.[37]

Standard Cow Milk-Based Formulas

③ Cow milk-based formulas are consumed by most US non-breastfeeding infants; although there is increasing usage of other types of infant formulas. Neither whole, reduced fat, or skim cow or goat milk is suitable for infant nutrition without modification. Standard, cow milk-based formulas contain primarily lactose; modified cow milk protein (80% casein, 20% whey); vegetable oils (no MCT); DHA and ARA; and vitamins, minerals, and other nutrients to meet the needs of most infants. Lactose is added to improve the carbohydrate-to-protein ratio, and the butter fat in cow milk is replaced with vegetable oils to improve absorption. If ready-to-feed or mixed to the standard concentration, they generally provide 20 kcal/oz (2.8 kJ/mL). Prebiotics, probiotics, lutein, and other substances separately or in proprietary blends may be added to better mimic human milk depending on the product. There are many formulas with modifications for altered needs in this category (Table e21-6).

Partially Hydrolyzed Whey, Cow Milk-Based Formulas

Some formulas are cow milk-based but contain 100% enzymatically hydrolyzed whey protein, which more closely mimics human milk (~82% whey) (Table e21-6). Hydrolysis makes the protein less antigenic than non-hydrolyzed cow milk; however, they are not recommended for infants with cow milk protein allergy. These products are marketed as being more like human milk and easier to digest. They are nutritionally interchangeable with other standard, term infant formulas. They may be useful in infants with excessive gas or colic on another term infant formula. They have a more pleasant smell and appearance than other cow milk-based formulas.

Lactose-Free or Lactose-Reduced Cow Milk-Based Formulas

Lactose has prebiotic effects, softens stools, and enhances water, sodium, and calcium absorption, but it is not essential. While primary (congenital) lactase deficiency is rare, lactose concentrations begin to decrease after 3 years of age, and some children will show signs of lactose intolerance as young as 3 to 5 years of age. By adulthood, a large percentage of adults have lactose intolerance. Secondary disaccharidase deficiency, including lactase, can occur after a severe diarrheal illness, moderate-to-severe enterocolitis as seen in patients with *Clostridioides difficile* or Hirschsprung's disease, and other viral or bacterial GI infections or inflammation. Lactase is generally the first enzyme affected and the last to recover. Because bacteria in the colon ferment sugars to carbon dioxide and short chain fatty acids, lactose intolerance can lead to watery, explosive, painful (acidic) stools; vomiting; abdominal distention; and crampy abdominal pain.[15]

The term, *lactose-free*, applies to many formulas intended for use in infants and children because many extensively hydrolyzed and all soy formulas are lactose-free (Table e21-6). Cow milk-based formulas can be made lactose-free or lactose-reduced (20%-30% of standard cow milk-based formulas) by enzymatic hydrolysis. These formulas have corn syrup solids and/or sucrose rather than lactose and are intended for use in infants with intolerance to cow milk-based formulas when the symptoms are concerning for lactose intolerance.

Only formulas that are 100% lactose-free can be used in infants with galactosemia, an autosomal recessive inborn error of metabolism in which galactose cannot be properly metabolized due to a deficiency of galactose-1-phosphate uridyltransferase (GALT), leading to galactose accumulation in the blood.[31] These infants present within a few days of life with jaundice, poor feeding, and vomiting. Galactosemia is detected via a standard newborn screen, but the symptoms may develop before the results are available.

Pre-Thickened (Added Rice Starch) Formulas

Formulas with added rice starch (Table e21-6) were designed specifically for infants with GER which affects 20% to 40% of all infants to some degree. For years, infant formula has been thickened with cornstarch or rice cereal to attempt to keep it in the stomach after ingestion. Problems with adding rice cereal to a formula include inconvenience, difficulty in sucking the thickened formula from the bottle requiring making the bottle's nipple hole larger, increased coughing during feedings, excessive energy intake (each tablespoon rice cereal provides as many as 60 calories [250 J] from carbohydrate alone), delayed gastric emptying and concerns for arsenic exposure. Rice readily absorbs arsenic from the environment, about 10 times more of it than other grains. Arsenic has been found in all brands of infant rice cereal tested, and lower concentrations have been noted in all brands of non-rice and multigrain cereals.[15,38]

Formulas with added rich starch contain 30% rice starch. These formulas are much less viscous in the bottle than formula thickened with rice cereal (viscosity is about 30 times that of non-thickened formula). The formula thickens substantially (about 100-fold) when exposed to the acidic pH in the stomach. Thickening and efficacy depend on having an acidic gastric pH: viscosity increases greatly at a pH less than or equal to 5.5. The use of an acid suppressing agent may decrease the efficacy of these products; thus, they are intended for use prior to the pharmacologic GER therapy. Decreased regurgitation has been documented with these formulas; of note, only 4% were receiving concomitant acid suppression.[39] Pre-thickened formulas are probably no more effective for GER than standard term formulas thickened with corn starch or rice cereal, but they offer the important advantage of convenience and more balanced nutrition. Additionally, pre-thickened formulas flow freely through standard nipples decreasing the work required to suck the formula from the bottle. Thickened feeds (added rice formulas or adding rice cereal to a formula) are not recommended for premature infants born before 37 weeks gestation who have been discharged from the hospital in the past 30 days due to concern for necrotizing enterocolitis (NEC).[23,39]

Organic Formulas

The number of infant formulas labeled as *organic* continues to increase (Table e21-6), and their global market share continues to rise. The global organic infant formula market is expected to reach $7.7 billion (USD) by 2023.[40] The Organic Foods Production Act of 1990 mandates that the US Department of Agriculture (USDA) govern the standards for organic products. Any product labeled *certified organic* must contain at least 95% organically produced or processed agricultural products. These products are certified free of chemicals and may be preferred by caregivers. Cost and inclusion of genetically modified (GMO) ingredients may limit their use.

Follow-up Formulas

Nutrient needs change as infants age and formula is no longer the sole source of nutrition. Most cow milk- and soy-based infant formulas are available in formulations modified for use by older infants and toddlers (usually 9-24 months of age). These are referred to as *follow-up, follow-on,* or *toddler* formulas (Table e21-7). Toddler formulas generally provide similar calories but more calcium and phosphorus (190%-300%) and iron (11%-33%) than term formulas. Some formulas also have increased protein and certain vitamins. These products provide no advantages over continuing a standard formula until 12 months of age followed by transitioning to whole cow milk; thus, the choice to use one of these formulas is based solely on caregiver preference and cost.[41] Despite no clearly defined role for these *toddler* formulas, they continue to have good global sales due to extensive marketing.[42]

Specialty Infant Formulas

Formulas for Preterm Infants

④ When sufficient maternal or donor milk is not available, specific formulas designed for preterm low birth weight infants can be used to meet their unique nutritional needs. Formulas marketed for premature infants (Table e21-8) supply nutrients needed to promote growth and body composition changes that mimic that of a normal fetus through gestation. Lactase activity rises relatively late in fetal life; thus, premature infants have reduced lactose digestion compared to term infants. Formulas intended for premature infants have a higher caloric density, less lactose, more MCT (40%), and more protein with a higher percentage of whey (whey:casein 60:40), and more sodium, potassium, phosphorus, calcium, vitamins A and D, zinc, and folic acid than term formulas. The use of these formulas in premature infants improves growth (weight, length, and head circumference), bone mineralization (near intrauterine accretion rates), and biochemical indices of nutrition status compared to unfortified human milk or term infant formulas.[43]

TABLE e21-8

Formulas for Premature Infants

Formula	Energy kcal/dL (kcal/oz)	Protein g/dL	Fat g/dL	Vitamin D IU/mL	Calcium mg/dL	Phosphorus mg/dL	Iron mg/dL
Mature human milk	65-70 (19.5 - 21)	1.03	3.5	Variable (based on mother's intake)	20 - 25	12 - 14	0.3 - 0.9
Premature Infant Formulas							
Similac® Special Care® 20	67.6 (20)	2.03	3.67	101.4	121.7	67.6	1.22
Similac® Special Care® 24	81.2 (24)	2.43	4.41	101.4	146.1	81.2	1.46
Similac® Special Care® 24 High Protein	81.2 (24)	2.68	4.41	121.7	146.1	81.2	1.46
Similac® Special Care® 30	101.4 (30)	3.04	6.71	182.6	152.2	101.4	1.83
Enfamil® Premature 20 Cal/fl oz	67.6 (20)	2.2	3.4	200	112	61	1.22
Enfamil® Premature 24 Cal/fl oz	81.2 (24)	2.7	4.1	240	134	73	1.46
Enfamil® Premature 24 Cal/fl oz HP	81.2 (24)	2.9	4.1	240	134	73	1.46
Enfamil® Premature 30 Cal/fl oz	101.4 (30)	3.3	5.1	300	167	91	1.83
Post-discharge Formulas							
Similac® Neosure®	74 (22)	2.1	4.1 (MCT 25%)	52	78	46	1.3
Enfamil® EnfaCare®/Enfamil NeuroPro™ EnfaCare®	74 (22)	2.1	4 (MCT 20%)	53	90	50	1.3
Protein Supplements							
Liquid Protein Fortifier per 6 mL (Abbott)	4	1					

MCT, medium chain triglycerides. For unit conversion purposes multiply values in kcal/oz by 0.1415 to give kJ/mL; values in mg/dL by 10 to give mg/L; and values in g/dL by 10 to give g/L.

Data from Abbott Nutrition, Abbott Laboratories, Columbus, OH; Mead Johnson Nutrition, Glenview, IL.

Formulas for preterm infants are generally available in ready-to-use bottles primarily for in-hospital use; however, these formulas may be used after discharge in selected high-risk infants. Most state WIC programs will supply these formulas for infants that meet specific criteria for their use. A preterm infant will receive one of these formulas until reaching a weight of at least 1,800 g to 2,000 g (~4-4.4 lb). Infants with bronchopulmonary dysplasia, cardiac anomalies, or other conditions that increase nutrition needs may benefit from continuing these formulas longer. Although the standard caloric density of these products is 24 kcal/oz (3.4 kJ/mL), they are available as 20 kcal/oz (2.8 kJ/mL), 24 kcal/oz (3.4 kJ/mL) with high protein, and 30 kcal/oz (4.2 kJ/mL). The higher concentration formulas can be fed directly or mixed with lower concentration formulas or human milk to increase caloric density and avoid the use of powdered supplements.

Post-Discharge Premature Infant Formulas

Few studies have evaluated the nutrition needs of premature babies after discharge. Many infants (as many as 79% in some series) leave the neonatal ICU having experienced poor growth with a weight-for-age less than the 10th percentile at 36 weeks postconceptional age.[44] It is generally assumed that with the need for continued catch-up growth in these infants, their nutrition requirements are higher than their term peers. Post-discharge preterm infant formulas were developed to span the gap between term and preterm formulas. The European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) advocates the use of these post-discharge formulas for preterm infants not receiving human milk who have not gained adequate weight at discharge until 40 to 52 weeks post-conceptional age, especially those who would not tolerate the larger volume of feedings needed with a 20 kcal/oz (2.8 kJ/mL) formula.[45] The standard caloric concentration of these formulas is 22 kcal/oz (3.1 kJ/mL), and they provide higher amounts of protein, calcium, phosphorus, and vitamins than term formulas (Table e21-8). Typically, if one of these formulas is used, additional vitamin and iron supplementation is not required. If a term infant formula or unfortified human milk is used for post-discharge feeding, additional vitamin and mineral supplementation may be required. Infants are generally transitioned to these formulas at a weight of 1,800 to 2,000 g or 34 weeks postconceptional age. A common practice is to continue a post-discharge formula until between 9 and 12 months corrected gestational age, but careful attention to growth velocity is important to avoid excessive *catch-up* weight gain.

Two meta-analyses that evaluated the use of post-discharge formulas compared to standard term formulas in preterm infants after discharge did not show a significant difference in growth outcomes, but the trials evaluated were heterogeneous.[46,47] The use of these formulas has been associated with lower fat mass, corrected for body size, at 6 months corrected age when compared to term formula or human milk.[48] This difference in central adiposity may have implications for obesity in later life. Growth during late infancy and childhood is a major determinant of later health.[49]

Soy Protein-Based Formulas

Soy-based formulas have been available in the United States since the 1920s. Despite their long-term availability, there are few true indications for soy-based infant formulas. However, approximately 12% to 20% of infants receiving formula are receiving a soy-based formula.[50] Additionally, the increased demand for more organic baby food products and plant-based diets is expected to stimulate a ~3% increase in global sales of soy-based formulas by 2028.[51] Soy formulas (Table e21-6) contain sucrose; corn syrup solids; corn maltodextrin; soy protein supplemented with methionine, carnitine, and taurine; and vegetable oils, including soy, sunflower, safflower, and coconut. DHA and ARA are routinely supplemented. They are free of cow milk protein, casein, whey, sucrose, and lactose. Soy formulas have a high concentration of phytates (antioxidant substances found in plants) and about 30% of phosphorus binds to these phytates; thus, soy formulas are supplemented with 20% more calcium and phosphorus than cow milk-based infant formulas.[52] Soy phytates and fiber oligosaccharides also bind iron and zinc; thus, soy formulas are supplemented with higher amounts of iron and zinc than cow milk-based formulas. With the current formulations, bone mineralization and serum calcium, phosphorus, and alkaline phosphatase concentrations in infants consuming them are equivalent to term infants fed cow milk-based formulas through 12 months of age.[52]

Soy-based formulas can be used in infants with lactose intolerance, galactosemia, and cow milk protein allergy, and if the caregiver prefers a vegan or vegetarian option. Because they are sucrose-free, they can be used in infants with sucrase-isomaltase deficiency, a rare genetic disorder. The use of soy formulas in patients with cow milk protein allergy is controversial. Sensitivity to soy protein develops in 7% to 35% of infants with enteropathy or enterocolitis associated with cow milk allergy, especially if younger than 6 months.[52] No benefit has been demonstrated with the use of soy protein-based formulas in atopic disease or infantile colic or fussiness, but there are few contraindications if caregivers choose to use them.

Soy formulas are contraindicated in premature infants weighing less than 1,800 g due to slower growth and decreased bone mineralization (osteopenia) even with the additional calcium and vitamin D added to these products. This effect on bone formation is partially due to the higher aluminum content of soy-based formulas. Aluminum can accumulate with kidney insufficiency and compete with calcium for absorption; thus soy-based formulas should be avoided in premature infants and infants with kidney dysfunction.[52] Infants with cystic fibrosis should not receive soy formulas because of worse nutrition outcomes observed with these formulas.

Soy-based infant formulas contain soy isoflavones and phytoestrogens which has raised concerns related to sexual development and reproductive health as well as immune and thyroid function later in life. These concerns are now considered unfounded. There are no differences in adult weight or height, age of puberty onset, fertility, or immune function in long-term assessment of children who receive soy-based formulas.[52,53]

Infants with congenital hypothyroidism receiving thyroid supplementation should not be given soy products with thyroid replacement therapy as the isoflavones interfere with thyroid hormone absorption. It is best to completely avoid soy-based infant formula in infants with hypothyroidism requiring thyroid hormone supplementation. However, if soy formula use is unavoidable, higher thyroid hormone dosages may be needed and careful monitoring of thyroid function (free thyroxine [free T_4], thyroid stimulating hormone [TSH]) is required.[53]

Extensively Hydrolyzed Protein Formulas

⑤ Some infants will require specialized formulas with altered macronutrients due to cow milk and soy protein sensitivities or conditions which lead to impaired nutrient digestion, absorption, or utilization (Table e21-9). The protein in these *extensively hydrolyzed* formulas has undergone heat-treated enzymatic hydrolysis resulting in small peptides (di-, tri-, and short chain) and free amino acids. These products are often differentiated based on the percentage of MCT in the product (0%-60%); those with more MCT may be used in patients with generalized malabsorption syndromes. These formulas are typically less palatable and more expensive than other infant formulas.

TABLE e21-9

Specialty Formulas for Term or Near-Term Infants[a]

Formula	Macronutrient Source			Other	Indications
	Carbohydrate	Protein	Fat		
Extensively Hydrolyzed Formulas (semi-elemental, hypoallergenic)					
Similac® Alimentum®	Maltodextrin, sucrose, tapioca starch	Casein hydrolysates, cystine, tyrosine, tryptophan	MCT 33%; safflower and soy oil	Reduced lactose; corn-free	Malabsorption, intractable diarrhea, short bowel syndrome, cystic fibrosis, biliary atresia; cow milk protein allergy
Nutramigen® (Liquids)	Corn syrup solids, modified corn starch	Casein hydrolysates	Corn oil 100%		
Nutramigen® Enflora™ LGG®			MCT 10%	*Lactobacillus rhamnosus GG*	
Pregestimil®	Corn syrup solids, modified tapioca starch	Casein hydrolysates	MCT 55%, corn oil		

Gerber® Extensive HA®	Maltodextrin, potato starch	Whey protein	MCT 49%; soy, safflower, palmitic, and vegetable oil	*Bifidobacterium lactis*	
Free Amino Acid Formulas (elemental, hypoallergenic)					
Elecare®	Corn syrup solids	Free amino acids	MCT 33%		Malabsorption, intractable diarrhea, short bowel syndrome, cystic fibrosis, biliary atresia, severe food allergies, cow milk protein allergy, eosinophilic esophagitis
Neocate® Syneo® Infant	Corn syrup solids	Free amino acids	MCT 8%; sunflower and canola oil	*Bifidobacterium breve*, FOS, inulin	
Neocate® Infant DHA/ARA					
Alfamino® Infant	Corn syrup solids, modified tapioca starch	Free amino acids	MCT 43%		
PurAmino™	Corn syrup solids	Free amino acids	MCT 33%; sunflower and soy oil		

ARA, arachidonic acid; DHA, docosahexaenoic acid; FOS, fructooligosaccharides; MCT, medium chain triglycerides.

[a] Not intended to be a complete listing; check manufacturers' websites for additional products and to verify content.

Data from Abbott Nutrition, Abbott Laboratories, Columbus, OH; Mead Johnson Nutrition, Glenview, IL; Nestlé SA, Vevey, Switzerland; Nutricia Advanced Medical Nutrition, Schiphol, the Netherlands.

Common indications for these products include cow milk protein allergy, cystic fibrosis, biliary atresia, short bowel syndrome, and generalized malabsorption. About 10% of patients with cow milk or soy protein will react to extensively hydrolyzed protein formulas. These patients will require a 100% amino acid-based product. These formulas are generally less palatable; thus acceptance varies. They are also much more expensive than other formulas. These formulas are not recommended for colic or GER due primarily to cost and palatability, but for an infant with severe symptoms, a short trial (1-2 weeks) is appropriate. The calcium and phosphorus content of these formulas is not adequate for premature infants; thus, supplementation or fortification may be required if a premature infant requires one.

Free Amino Acid Formulas

Amino acid-based formulas are the most hypoallergenic because protein is broken down to amino acids (no peptides). They may be referred to as *elemental* which refers only to the protein component. They are indicated in children with cow milk, soy protein, or multiple food protein allergies, especially those with proctocolitis or eosinophilic esophagitis (EOE), a chronic immune-mediated inflammatory condition.

Proctocolitis manifests as rectal bleeding with onset between 2 and 8 weeks of age in breast- or formula-fed infants who are otherwise healthy (no vomiting, diarrhea, feeding difficulties, or growth issues). Mothers of infants with proctocolitis who wish to continue breastfeeding must remove all cow milk and soy from their diets. After eliminating cow milk and soy from the diet, improvement can be seen in just a few days and usually within 2 weeks.

In patients with EOE, three dietary regimens are effective for normalization of the esophageal biopsy in most patients: strict use of an amino acid–based formula; dietary restriction based on multimodality allergy testing; and dietary restriction based on elimination of likely food antigens (milk, wheat, soy, eggs, nuts, fish/seafood).[54,55]

High MCT-Containing Formulas

In several infant formulas, a high percentage of the fat is provided as MCT; these formulas also contain higher concentrations of fat-soluble vitamins. The protein component is not hydrolyzed, however, making them unsuitable for patients with generalized malabsorption (short bowel syndrome). Formulas with high MCT concentrations (see Table e21-10) are used in patients with abnormal lymphatic drainage such as chylous ascites, chylothorax,[56] and lymphangiectasia. Because MCT do not form micelles, they are readily absorbed throughout the intestine directly into the bloodstream, bypassing the lymphatic system. Thus, a diet very high in MCT (and very low in LCPUFAs) may dramatically decrease lymphatic flow; thereby decreasing chylous drainage. These formulas are also used in patients with pancreatic insufficiency (cystic fibrosis), bile acid deficiencies (biliary atresia, cholestatic jaundice, intestinal resection), and long chain fatty acid oxidation defects (long chain acyl CoA dehydrogenase deficiency [LCAD], carnitine palmitoyl transferase deficiency [CPTD], and primary and secondary lipoprotein lipase deficiency [hyperlipoproteinemia type 1]). Due to their low LCPUFA content, these formulas provide insufficient essential fatty acids; thus, long-term use confers a substantial risk of EFAD. Formulas high in MCT have a higher osmolality which may cause loose stools or diarrhea.[36]

TABLE e21-10

High MCT-Containing Formulas

Formula	Carbohydrates	Protein	Fat
Enfaport^{TM} (liquid, 30 kcal/oz [4.2 kJ/mL])	Corn syrup solids; lactose-free; not galactose-free	Whey 60% Casein 40% (non-hydrolyzed)	MCT 83% DHA, ARA
Monogen® (powder)	Maltodextrin	Cow milk Whey predominant (non-hydrolyzed)	MCT 84% DHA, ARA
Portagen®[a] (powder)	Corn syrup solids, sucrose	Cow milk (non-hydrolyzed)	MCT 87%

ARA, arachidonic acid; DHA, docosahexaenoic acid; LCT, long chain triglycerides; MCT, medium chain triglycerides

[a] Not recommended for infant nutrition.

Data from Mead Johnson Nutrition, Glenview, IL; Nutricia Advanced Medical Nutrition, Schiphol, the Netherlands.

Enfaport® is available only as a 30 kcal/oz (4.2 kJ/mL) liquid formulation. If used in an infant younger than 1 year of age, dilution is required, and proper caregiver and staff education must be ensured. Portagen® is not recommended as an infant formula, especially for infants who may be immunocompromised, due to the risk of contamination associated with the inability to fully sterilize powders brought to light with the death of a neonate caused by *Enterobacter* (now *Chronobacter) sakasakii* contamination of formula powder. Monogen® is also only available as a powder.

Low Mineral/Metabolic Formulas

A number of formulas are manufactured specifically for infants with inborn errors of metabolism or other metabolic diseases. Examples of these formulas and their indications are provided in Table e21-11. One formula in this category is Similac PM® 60/40, a low mineral (calcium, phosphorus, iron, potassium) formula for use in infants with kidney dysfunction or hypercalcemia. This formula is a whey protein concentrate with sodium caseinate, lactose, high oleic safflower, soy, and coconut oils. It is vitamin D-free for use in patients with William’s syndrome, neonatal hyperparathyroidism, and osteopetrosis, conditions associated with hypercalcemia. Calcilo-XD® is also a low calcium formula for use in patients with hypercalcemia. The calcium-to-phosphorus ratio (2:1) and low sodium concentration make the formula less suitable for low birth weight infants, and supplementation may be required if used in this population.

TABLE e21-11

Formulas for Inherited Metabolic Disorders[a]

Product	Indication	Characteristic
3232 A (MJ)	Carbohydrate intolerance; disaccharidase deficiency	Sugar must be added
Calcilo XD® (A)	Hypercalcemia, Williams syndrome, osteopetrosis, primary neonatal hyperparathyroidism	Low calcium, vitamin D-free

Cyclinex®-1/Cyclinex®-2 (A) WND® 1/WND® 2 (MJ)	Urea cycle disorders, gyrate atrophy, HHH syndrome	Non-essential amino acid-free
Glutarex®-1/Glutarex®-2 (A) GA (MJ)	Glutaric aciduria type 1	Lysine- and tryptophan-free
Hominex®-1/Hominex®-2 (A) HCY 1/HCY 2 (MJ)	Homocystinuria, hypermethioninemia	Methionine-free
I-Valex®-1/I-Valex®-2 (A) LMD (MJ)	Leucine metabolism disorders	Leucine-free
Ketonex®-1/Ketonex®-2 (A) BCAD 1/BCAD 2 (MJ)	Maple syrup urine disease (MSUD), beta-ketothiolase deficiency	Isoleucine-, leucine-, and valine-free
PFD Toddler/PFD 2 (MJ) Pro-Phree® (A)	Amino acid metabolic disorders	Protein-free
Phenex®-1/Phenex®-2 (A) Phenyl-Free® 1 / Phenyl-Free® 2 / Phenyl-Free® 2 HP (MJ)	Phenylketonuria (PKU)	Phenylalanine-free
Propimex®-1/Propimex®-2 (A) OA 1/OA 2 (MJ)	Propionic or methylmalonic acidemia	Methionine- and valine-free; low isoleucine and threonine
Provimin® (A)	Abetalipoproteinemia, many others	Protein, vitamins, minerals, iron
RCF® (A)	Carbohydrate intolerance	Sugar must be added
Similac® PM 60/40 (A)	Kidney disease, hypercalcemia	Low in calcium, phosphorus, iron, potassium
Tyrex®-1/Tyrex®-2 (A) Tyros 1/Tyros 2 (MJ)	Tyrosinemia type I, II, or III	Phenylalanine- and tyrosine-free

[a] Not intended to be a complete listing; check manufacturers' web sites for additional products and to verify content.

Data from Abbott Nutrition, Abbott Laboratories, Columbus, OH; Mead Johnson Nutrition, Glenview, IL.

Several products are carbohydrate-free (Table e21-11). These formulas are used in infants who are unable to tolerate the carbohydrates in human milk or infant formulas due to congenital disorders of carbohydrate metabolism and absorption (eg, disaccharidase deficiency). These products contain extensively hydrolyzed cow milk and soy protein, vegetable oils (82% MCT), tapioca starch, but no carbohydrates. Simple sugars (glucose polymers, fructose) are added gradually to improve tolerance. Generally, the sugar is added to make the caloric density the same as standard infant formula (20 kcal/oz [2.8 kJ/mL]). These products may not supply adequate essential fatty acids.

From

The ketogenic diet is an effective non-pharmacological treatment for drug-resistant childhood seizures.[57] A ketogenic diet mimics the body's response to starvation, when the body shifts to a ketotic state, shifting metabolism from carbohydrate to fat utilization for fuel. The ketogenic diet is a high fat (71%-90% of energy) and low carbohydrate (5%-19% of energy) that contains adequate protein to support growth. Each component of the diet is calculated in a specific proportion by a trained registered dietitian. While a small amount of human milk or standard infant formula may be allowed, most infants will receive a formula specifically designed for the ketogenic diet such as KetoCal™ 4:1 and KetoCal™ 3:1 (Nutricia, Gaithersburg, MD) and KeoVie™ 4:1 and KetoVie Peptide™ 4:1 (Cambrooke Therapeutics). The ratio in the name refers to the ratio of fat (g) to carbohydrates plus protein (g). For example, in KetoCal™ 3:1, for every 3 g fat, there is 1 g of carbohydrates plus protein. Classically, children younger than 2 years of age receive a 3:1 formula and children 2 to 12 years of age receive a 4:1 formula; however, this may vary. Patients on ketogenic diets must receive frequent monitoring of growth, electrolytes, liver function, serum lipids, carnitine, vitamins, and trace minerals. Most patients will also require a carbohydrate- and lactose-free supplement (to avoid disruption of the ketotic state) to provide additional selenium, vitamin D, B vitamins, magnesium, and iron. If supplements or medications are required that cannot be given in a sugar-free form, the dietitian can calculate the nutrition prescription with these carbohydrates included.

OTHER NUTRIENT CONSIDERATIONS

⑥ Two nutrients, iron and vitamin D, are of particular importance in infant nutrition.

Iron

Term babies are born with adequate iron stores; for premature infants, the younger the gestational age, the greater the total body iron deficit at birth. Iron deficiency is associated with anemia and poor neurodevelopmental outcomes. Most infant formulas are fortified with iron, and infants receiving one of these formulas usually do not require additional iron supplementation. Human milk, however, is low in iron and exclusively breastfed infants require iron supplementation.

Premature infants receiving human milk who are 1 month of age should receive iron at a dose of 2 mg elemental iron/kg daily through 12 months of age. Up to 3 mg elemental iron/kg daily may be needed in low and very low birthweight infants. Premature infants who are formula-fed may require supplementation depending on the formula.[15] Iron supplementation (1 mg/kg daily) is recommended beginning at 4 months of age for term infants receiving exclusive human milk feeding or less than 50% of their daily feedings as iron-fortified formula.[15,58] Introduction of iron-fortified solid foods at 6 months of age generally provides an adequate supply of iron, and the need for continued supplementation should be re-addressed at that time. Routine monitoring of iron studies (serum ferritin, transferrin saturation, serum iron) is not warranted unless anemia does not respond after 1 month of appropriate iron supplementation.[58]

Vitamin D

Vitamin D and calcium deficiencies are common worldwide causing nutritional rickets and osteopenia, which can dramatically impact growth, development, and overall health. Despite ready access to vitamin D supplements, cases of rickets are still documented in the United States, often in exclusively breastfed infants not receiving vitamin D supplementation. Current AAP and global recommendations recommend that all infants receive 400 international units (10 μg) daily starting a few days after birth regardless of their mode of feeding until they are consuming at least 32 oz (~950 mL) of vitamin D-fortified formula or cow milk[59,60] unless the mother ingests at least 6,400 international units (160 μg) daily.[61] After 12 months of age, the recommended intake in children and adolescents is 600 international units/day. Liquid vitamin D supplements are unpalatable, and caregivers often discontinue the supplement due to vomiting or refusal by the infant. Education regarding the importance of vitamin D for bone health and other outcomes is important.

Monitoring of vitamin D serum concentrations (25-OH-vitamin D) is not indicated in most infants and children. For those with risk factors for vitamin D deficiency (cystic fibrosis, short bowel syndrome, biliary disease, long-term parenteral nutrition), target ranges have been defined as: sufficient, > 20 ng/mL (50 nmol/L); insufficient, 12 to 20 ng/mL (30 to 50 nmol/L); and, deficient, < 12 ng/mL (30 nmol/L).[60] Vitamin D toxicity is uncommon but hypercalcemia and hypercalciuria can be seen with a serum 25-OH-vitamin D concentration greater than 100 ng/mL (250 nmol/L) and a decreased serum parathyroid hormone (PTH) concentration.[60]

Non-Nutrient Additives in Infant Formulas

(7) Human milk contains a variety of non-nutritive compounds with specific bioactive characteristics; formula manufacturers continue to modify their products to include these compounds.[62] Non-nutritive additions to formulas, and even some nutritive ones, have been questioned due to the increase in manufacturing costs without definitive evidence to support their need.

Prebiotics and Probiotics

A healthy gut is of major importance in infancy as it contributes to growth and development of immunity. Microbial colonization of the GI tract starts before or right after birth. It is well-established that human milk- and formula-fed infants have different intestinal microbiomes.[62–64] To try to mimic the effect of human milk on the GI microbiome, both pre- and probiotics have been added to some infant formulas.

Prebiotics are indigestible, fermentable carbohydrates (oligosaccharides) that are not fully digested in the small intestine. Prebiotic oligosaccharides are the third most prevalent component of human milk.[65] They promote the growth and activity of beneficial gut flora, lactobacilli, and bifidobacterium and prevent proliferation of pathogenic bacteria. Examples of prebiotics include inulin, FOS, and GOS. Fermentation of these oligosaccharides produces short chain fatty acids that are used by the colonocytes for energy, thus protecting the mucosal barrier. Term infant formulas supplemented with prebiotics promote growth similar to infants fed human milk or non-supplemented formula.[63] Infants receiving the prebiotic-containing formula have an increased frequency of softer stools than those fed non-supplemented formula, but stools are comparable to those of infants fed human milk.[65]

Probiotics are live, nonpathogenic microorganisms (bacteria, fungi) with beneficial effects on the host. They interfere with the adherence of pathogenic bacteria, increase intestinal immunologic barrier, and modulate the inflammatory response. Probiotics modulate intestinal inflammation by inhibiting pathogen growth, improving mucosal health and integrity, and regulating intestinal immune response. Human milk is an important source of beneficial bacteria that colonize the infant gut. Human milk contains between 10^3 and 10^6 bacteria per milliliter depending on the analysis method used. Human milk contains a variety of probiotics; *Bifidobacterium spp.* predominate, but *Lactobacillus spp.,* are also found in high concentrations.[63] *Lactobacillus rhamnosus GG*, also found in the intestine of breastfed infants, has been found to decrease diarrhea in infants receiving antibiotics.

Some infant formulas are supplemented with probiotics, including *Bifidobacterium lactis* or *L. rugieri,* to more closely mimic human milk and to promote a healthy immune system. *B. lactis* has been associated with a decreased risk of NEC likely due to its protective effects on the gut barrier function. Advanced microencapsulation technology has allowed the bacteria added to infant formulas to be protected from destruction before reaching the site of action (colon).[66] While probiotics are found in human milk and considered safe, concerns remain regarding their use in infants who are immunocompromised, chronically debilitated, or seriously ill with indwelling medical devices.[67]

Lutein

Infancy and early childhood are critical times for eye and brain development. The retina and the brain share the same embryological origin from the neural tube formed around the fourth week of gestation.[68] Lutein is found in high concentrations in the macula of the eye and is the predominant carotenoid in the brain.[69] In the eye, lutein is an antioxidant and a high-energy blue light filter. Age-related differences in the transmission of optic radiation to the retina have been observed for blue light (400-500 nm), the most energetic wavelengths of visible light radiation. The retina of a young child is exposed to much more blue light than an older person.[68]

Lutein is a lipophilic xanthophyll dietary carotenoid found in many fruits, vegetables, and human milk. Animals do not synthesize carotenoids de novo; thus, infants must consume lutein through human milk or supplemented infant formulas. Lutein supplementation has the potential for long-term protection again blue light damage to the eyes and may be important for cognitive function across the lifespan.[68,69] Lutein supplementation may improve brain network connectivity, especially in the default and sensory-motor and default and dorsal attention and visual and somatosensory networks.

Lutein is a safe molecule with an extensive consumption from the diet. Lutein is GRAS (generally recognized as safe) in the United States for adding to foods, including infant formulas. The European Food Safety Agency (EFSA) has established the safety and bioavailability of lutein in infant formulas.

Lactoferrin

Lactoferrin is the major whey protein in all mammalian milk. There is a high (~70%-80%) structural and functional similarity between bovine lactoferrin (bLF) and human lactoferrin. Functions of lactoferrin include antibacterial/antiviral activity, antioxidant activity, immunomodulation, trophic effects on enterocytes and enteric Caco2 cells, and benefits on the GI microbiota.[70–72] Cow milk has low concentrations of bLF, so some manufacturers have supplemented cow milk-based formulas with bLF to more closely mimic human milk. Formulas supplemented with bLF, prebiotics, DHA, and ARA compared to non-supplemented term infant formula result in equivalent growth but softer stools, consistent with stools of breast-fed infants.[71] In some, discontinuation of the supplemented formula occurs secondary to fussiness and gas, which may also occur with formulas supplemented with prebiotics alone.[71] Infants receiving formula supplemented with bLF compared with non-supplemented formula have a decreased prevalence of acute GI symptoms (diarrhea, vomiting) and decreased days with acute respiratory symptoms (nasal congestion, cough).[72] The FDA considers bLF as GRAS.

Milk Fat Globule Membrane (MFGM)

The lipid droplets of milk fat globules (including those found in breast milk) are stabilized by a three-layered membrane, the milk fat globule membrane (MFGM), which maintains triglyceride dispersion in the aqueous phase of the milk. The MFGM is composed primarily of polar lipids (phospholipids, glycosphingolipids), proteins (mainly glycoproteins), and apolar lipids (cholesterol, cerebrosides).[73] MFGM is produced by the mammary gland epithelium, has antibacterial and antiviral activity, and improves GI maturation and central nervous system myelination.[73] An extensive review of the role of MFGM in infant health and development can be found elsewhere.[74]

MFGM is a component of bovine milk that has historically been discarded in infant formula preparation as most formulas contain vegetable oils with much different structures. Recent improvements in manufacturing technology have allowed concentration of bovine MFGM, making it feasible to add to infant formula. Infants receiving formula supplemented with MFGM (also supplemented with bLF) had an accelerated neurodevelopmental profile at day 365 and improved language subcategories at day 545. There were also fewer diarrhea and respiratory-associated adverse events through 545 days of age.[75]

PEDIATRIC FORMULAS (1-13 YEARS)

8 Enteral formulas are available for children who need supplemental nutrition beyond a regular diet in most of the infant formula categories discussed and are used for similar indications (Table e21-12). These products are available in caloric densities of 18.9 kcal/oz to 45 kcal/oz (0.63-1.5 kcal/mL or 2.7-6.4 kJ/mL, respectively) and have vitamin and mineral contents suitable to meet the needs of older children. Children older than 13 years of age will generally receive a product intended for use in adults (Chapter 166). The choice of formula depends on age, GI function, previous tolerance, allergies, nutrition requirements, and organ function.

TABLE e21-12

Formulas for Children 1-13 Years of Age[a]

Formula	Mfr	Macronutrient Source			Indications
		Carbohydrate	Protein	% Fat as MCT	

Standard Polymeric Formulas					
Pediasure® 1.0 Cal Pediasure® 1.0 Cal with Fiber Pediasure® 1.5 Cal Pediasure® 1.5 Cal with Fiber Pediasure® Grow & Gain Pediasure® Grow & Gain with Fiber Pediasure® Grow & Gain Organic Pediasure® Enteral Formula 1.0 Cal Pediasure® Enteral Formula 1.0 Cal with Fiber Pediasure Sidekicks® Pediasure® Pro Pediasure® Reduced Calorie	Abbott	Corn maltodextrin, sugar	Milk protein	-	Normal functioning GI tract
Nutren Junior® Nutren Junior Fiber®	Nestlé	Maltodextrin, sugar	Milk protein, whey (50%)	20%	
Boost® Kid Essentials™ Boost® Kid Essentials™ 1.0 Boost® Kid Essentials™ 1.5 Boost® Kid Essentials™ 1.5 with Fiber	Nestlé	Brown rice syrup, sugar	Milk protein	-	
Blenderized / Whole Food Formulas					

Compleat® Pediatric Compleat® Pediatric Reduced Calorie Compleat® Pediatric Organic Blends[b]	Nestlé	Brown rice syrup; fruits and vegetables; corn-free, low lactose	Milk protein; chicken powder; pea protein; soy-free	20%	Long-term tube feeding when whole food preferred; some can be used orally for patients with food allergies
Nourish[b,c]	functional formularies	Plant-based; dairy-, gluten-corn-free	Plant-based; dairy-, soy-free	Plant-based	
Pediatric Standard 1.2[b,c]	Kate Farms	Brown rice syrup; dairy-, gluten-corn-free	Pea protein; dairy-, soy-, nut-free	42%	
Pediasure Harvest™[b]	Abbott	Plant-based; dairy-, gluten- lactose-free	Plant-based; contains soy	Plant-based	
Extensively Hydrolyzed Formulas					
Pediasure® Peptide 1.0 Cal Pediasure® Peptide 1.5 Cal	Abbott	Corn maltodextrin	Whey hydrolysate	60%	Malabsorption, maldigestion, intractable diarrhea, short bowel syndrome, cystic fibrosis, biliary atresia
Peptamen Junior® Peptamen Junior® 1.5 Peptamen Junior® HP Peptamen Junior® Fiber Peptamen Junior® with Prebio™ Peptamen Junior® PHGG	Nestlé	Maltodextrin, cornstarch, sugar	Whey hydrolysate	60%	
Pediatric Peptide 1.0 Pediatric Peptide 1.5[b,c]	Kate Farms	Brown rice syrup; dairy-, gluten-, corn-free	Hydrolyzed pea protein; dairy-, soy-, nut-free	42%	

Compleat® Pediatric Peptide 1.5	Nestlé	Brown rice syrup; fruits and vegetables; corn-free, low lactose	Hydrolyzed pea protein	40%	
Nourish Peptide Formula	functional formularies				
Nutramigen® with Enflora™ LGG® Toddler	Mead Johnson	Corn syrup solids; lactose-, sucrose-free	Casein hydrolysate	-	
Amino Acid Formulas					
Elecare® Jr	Abbott	Corn syrup solids	Amino acids	33%	Malabsorption, intractable diarrhea, short bowel syndrome, cystic fibrosis, biliary atresia, severe food allergies
Neocate® Junior	Nutricia	Corn syrup solids	Amino acids	8%	
Neocate® Splash	Nutricia	Maltodextrin, sugar	Amino acids	1.8%	
PurAmino™ Jr / PurAmino™ Jr Vanilla	Mead Johnson	Corn syrup solids, modified tapioca starch	Amino acids	33%	
Vivonex® Pediatric	Nestlé	Maltodextrin, modified cornstarch	Amino acids	70%

Blenderized Formulas

Blenderized formulas have become increasingly popular in pediatrics as society places a higher value on more natural foods. These products may be preferred by some families because they more closely mimic "real food" for their child (psychosocial). Others may receive them due to intolerance to other formulas or for other perceived health benefits.[76] A blenderized diet could be homemade from whole foods, a mixture of a commercial formula with pureed foods, or a commercially available ready-to-use formula (see Table e21-12). Blenderized products are generally higher in fiber and may be beneficial in patients on long-term nutrition support, especially those with neurological deficits, who have a high incidence of constipation. To comply with the AAP and WHO recommendations for adding complementary foods to infants' diets, blenderized diets are generally not used in infants younger than 6 months of age. Whole cow milk should be avoided until 12 months due to the risk of GI bleeding, anemia, electrolyte imbalances, metabolic acidosis, and folic acid and iron deficiency.[15] Many blenderized formulas are thicker than other formulas and, if given via a small-bore feeding tube or if given via a feeding pump, may require dilution with water. The risk of bacterial contamination is high with these products, limiting their hang time (when continuous rather than bolus tube feedings are used).[76] Generally, these formulas are more expensive than other products due to the manufacturing process. Documentation of intolerance to other products may be required to obtain insurance coverage, and collaboration with a case manager, social worker, or registered dietitian may help to ensure that the family receives assistance.

HUMAN MILK AND INFANT FORMULA SAFETY

Human Milk

⑨ Expressed human milk and infant formulas must be handled and stored properly. Human milk should be stored in 2- to 4-ounce (60 to 120 mL) aliquots. Human milk may be stored at room temperature (up to 77°F [25°C]) for 4 hours, or if cleanly expressed, a maximum of 8 hours. Once a bottle is started, it should be consumed within 2 hours, and if not, the remaining may be refrigerated and used at the next feeding. While human milk can be stored in the back of the refrigerator, if it is not going to be used within 24 hours, it should be frozen. Human milk can be frozen in the back of a freezer with a separate door (0°F [-18°C]) for 9 months and in a chest or deep freezer (-4°F [-20°C]) for 12 months. Once thawed (by placing in a warm water bath, never in the microwave), human milk should be used within 24 hours.[15]

There may be considerable loss of fat, fat-soluble vitamins, and phospholipids when human milk is administered via a feeding tube. When using frozen and thawed milk, there is more loss than when using fresh, never frozen, milk. Expressed milk stored for 3 days is associated with less loss than when milk is fresh. For infants receiving human milk through a feeding tube, intermittent administration (bolus or intermittent infusion) is preferred over continuous infusion, if possible. For human milk feedings, the hang-time should not exceed 4 hours.[77]

Infant Formula

Formulas are available as powders requiring reconstitution, ready-to-use liquids, and concentrated liquids requiring dilution with water. Powders are not sterilized; thus, neonates in ICUs and immunocompromised infants should receive an alternative whenever possible. When powdered formula is used, it is important that proper preparation technique is used and that the reconstituted formula is stored properly. Boiling water should not be used to reconstitute powders as it may disrupt nutrient delivery and may not kill all organisms. Small quantities should be mixed at one time. If formula is mixed from powder, it should be stored in the refrigerator and discarded after 24 hours. Once a can of powder has been opened, unused powder should be discarded after 30 days. Unused ready-to-use or concentrated liquids should be discarded if not used within 48 hours. If used for tube feedings, formula should be allowed to hang at room temperature for no more than 4 hours unless chilled. Feeding tube bags with pouches for ice packs are available.

For infants with volume intolerance (GER, heart disease, liver failure), poor growth, or altered nutrient needs, formulas may be concentrated to a higher than standard caloric density by adding less water to a powder or concentrate or adding a modular component to a ready-to-use or prepared liquid (Table e21-13). In general, concentrating to more than 27 kcal/oz (3.8 kJ/mL) by adding less water is not recommended. Consultation with a registered dietitian is recommended when an infant's formula requires significant manipulation from the standard concentration. Concerns with concentrating formula beyond the standard density include vomiting, constipation, high renal solute load due to excessive protein, and excessive weight gain. Improper mixing to a concentration below the standard may result in diarrhea, poor weight gain, hyponatremia, and other electrolyte imbalances. Regardless of the feeding regimen, parents/caregivers should be educated and given written instructions on the proper preparation of their infant's formula (if not breastfeeding) prior to discharge from the hospital or leaving an office visit. Knowledge should be re-assessed at each visit with a healthcare provider, especially in an infant with growth faltering or other nutrition-related issues.

TABLE e21-13

Modular Nutrient Additives

Nutrient Supplied	Products Available
Carbohydrate	Moducal®, Polycose®, SolCarb®, corn starch[a]
Protein	ProMod®, Casec®, Beneprotein®, ProStat®, Essential Amino Acid Mix, Complete Amino Acid Mix
Fat	MCT Oil®, Microlipid®
Carbohydrate and fat	Duocal®
Pectin and carbohydrate	Banana Flakes®
Carbohydrate, fat (MCT/LCT), protein	MCTprocal™
Fiber	Nutrisource® Fiber, Benefiber®

[a] Glycemic index < 50; useful in ketogenic diet.

ORAL REHYDRATION

In the United States., fluid and electrolyte disturbances from acute gastroenteritis result in many outpatient visits and hospitalizations but only a small number of deaths each year. Rotavirus was the leading cause of viral diarrhea and the main cause of severe disease and hospitalization until the introduction of the rotavirus vaccine. In countries with the rotavirus vaccine, norovirus is now the leading cause of moderate to severe diarrhea, traveler’s diarrhea, and food poisoning outbreaks in children younger than 2 years of age.[78] In developing countries, acute diarrhea is common resulting in ~500,000 deaths in 2018, a number significantly less than the 4 to 6 million deaths reported in 1980, the year a pivotal article on the effectiveness of glucose and electrolyte solutions (oral rehydration solutions) was published.[79] Infants and young children become mildly to severely dehydrated more quickly due to higher fluid needs and higher frequency of poor oral intake with illness. Signs and symptoms of dehydration are listed in Table e21-14.

TABLE e21-14

Signs and Symptoms of Dehydration

Mild-to-Moderate Dehydration	Severe Dehydration
Restlessness	Lethargy
Irritability	Unconsciousness
Sunken eyes	Significant thirst, very dry mouth
Rapid pulse	Prolonged skin tenting
Increased thirst, dry mouth	Weak or absent pulse
Mild skin tenting	Low blood pressure
Decreased urine output	Minimal to no urine output
Dark urine	Poor capillary refill
Decreased tears	
Depressed fontanelle (young infants)	
Slow capillary refill	

⑩ Oral rehydration therapy (ORT) is a mainstay of treatment for mild-to-moderate dehydration; severe dehydration requires IV rehydration. The principles of ORT are simple: give fluid orally (or via nasogastric tube) that contains sodium and glucose, and the co-transport of glucose and sodium across the intestinal membrane will take water with it. Sodas and commercial juices cannot be used for ORT because they do not contain enough sodium or contain too much glucose or both. Additionally, the sugar in juice may result in more stool volume due to its osmotic effect. The original WHO recommended *standard osmolality* oral rehydration solution (ORS) contains a concentration of sodium of 90 mmol/L and glucose of 13.5 g/L resulting in an osmolality of 333 mOsm/L. In 2002, WHO amended its recommendation to use a ORS containing sodium 75 mEq/L (mmol/L) and glucose 13.5 g/L resulting in an osmolality of 245 mOsm/L (low osmolality ORS).[80] The reason for this change was that the higher osmolality solution increased stool output in a high percentage of patients due to its osmotic effects in the intestine. The lower osmolality solution is as effective as the higher one without dramatically increasing stool volume.[81] Polymer-based ORT solutions are marketed. These solutions contain *glucose polymers* in the form of whole rice, wheat, sorghum, and maize. Because amylase is generally not affected by diarrhea, amylase is available to slowly break down these starches into glucose, which then provides the carrier molecules for co-transport of sodium and water across the intestinal epithelium, resulting in rehydration of the extracellular fluid (see Chapter 68, "Disorders of Sodium and Water Homeostasis"). Comparison of glucose-based and polymer-based ORS has not demonstrated a significant difference in outcomes such as hyponatremia, vomiting, or the need for IV fluid.[82]

Despite CDC[83] recommendations for ORT for children with mild-to-moderate dehydration, use in the United States is limited. Advantages of ORT are that it can be administered in the home, reduces the need for outpatient and emergency department visits, requires less emergency department staff time, reduces the length of emergency department visits, avoids the placement of an IV catheter, and avoids the use of IV fluids. Contraindications to ORT include altered mental status due to aspiration risk, abdominal ileus, and underlying intestinal malabsorption syndromes (short bowel syndrome). Cost also is a consideration with ORT. Families may not be able to purchase the solution; thus, providing ORT in a clinic or emergency department setting may limit the overall cost to the patient. If a patient is unable to take the ORT solution by mouth, then a nasogastric tube may be placed, and the solution given via the tube. This method of administration has been effective and more cost-effective than IV therapy but may not be preferred by the patient or family.

Tables e21-15 and e21-16 provide volumes of intake and solutions used for ORT, respectively. The use of a commercially available product is preferred to the use of home recipes to limit errors, but commercial products are not readily available to all, and recipes are available online for homemade ORS. If the patient can sit up and drink, they can usually receive ORT. For mild dehydration, 50 mL/kg of ORT solution should be administered over the first 4 hours using a spoon, syringe, medicine cup, or other devices. A rule of thumb is 1 mL/kg (0.5 mL/lb) every 5 minutes. If the patient is thirsty and asks for more, it should be given. For moderate dehydration, 100 mL/kg (50 mL/lb) is recommended for the first 4 hours. While mild dehydration can be managed in the home, moderate dehydration should be managed in a physician's office or emergency department, and severe dehydration should be treated in a health care facility with IV fluids. After 4 hours, if the child has taken all the ORS, the patient may be sent home and maintenance fluids, calculated using the Holiday-Segar method (see Chapter 68), given until the illness resolves. Simplified, this is 1 oz (30 mL) per hour for infants, 2 oz (60 mL) per hour for toddlers, and 3 oz (90 mL) per hour for older children. It is also recommended that the child receive an additional 10 mL/kg (5 mL/lb) for every loose stool and 2 mL/kg (1 mL/lb) for every vomiting episode to prevent further dehydration.

TABLE e21-15

WHO Guidelines for Oral Rehydration in Children

Recommended Volume of ORT to Correct Dehydration		
Weight (kg)[a]	**Age**[a]	**ORS, mL in first 4 hours**[b]
Less than 5	Younger than 4 months	200-400
5-7.9	4-11 months	200-400
8-9.9	12-23 months	600-800
10-15.9	2-4 years	800-1,200
16-29.9	5-14 years	1,200-2,200
30 or more	15 years or older	2,200-4,000
Recommended Volume after Stooling to Prevent Dehydration		
Age (y)	**Recommended Volume (mL)**	**Maximum Daily Volume (mL)**
< 2	50-100	500
2-9	100-200	1,000
≥ 10	At least 100-200, but as much as desired	2,000

[a] Use age only if weight is not available.

[b] Volume for first 4 hours can also be calculated by multiplying the weight (kg) by 75.

TABLE e21-16

Oral/Enteral Hydration Solutions (examples only)

Product	Sodium (mEq/L)	Potassium (mEq/L)	Chloride (mEq/L)	Base (mEq/L)	CHO (g/L)	Osm (mOsm/L)	Other
Recommended Concentration	**60-90**	**15-25**	**50-80**	**8-12**	**Equal to sodium; < 111 mmol/L**	**200-310**	
Rehydration Solutions—replace fluid deficits

Signs of adequate ORT (rehydration) include no skin tenting or thirst, a strong pulse, and adequate urination. Once the patient is rehydrated, a regular age-appropriate diet should be initiated. Breastfed infants may continue to feed during ORT, but if held, then breastfeeding should be resumed as soon as ORT is complete. Early resumption of a regular diet does not worsen symptoms of diarrhea and may decrease its duration. Occasionally, if diarrhea is prolonged, a lactose-free infant formula may be considered for a few days, especially if the infant’s usual formula seems to worsen symptoms when feeding is reinstituted.

SELF-ASSESSMENT QUESTIONS

1. A 7-day-old infant is in the clinic today for the first well baby check. A review of the chart shows that the newborn screen was resulted as positive for galactosemia. The infant is currently being breastfed. Which of the following is the *best* approach for feeding this infant?

   A. Continue breastfeeding; educate mother to avoid cow milk

   B. Change to Enfamil® NeuroPro™ Infant

   C. Change to Similac® Pro-Total Comfort® 20

   D. Change to Enfamil® NeuroPro™ Gentlease®

2. A healthy, near-term neonate, born at 36 weeks estimated gestational age, will receive infant formula at discharge because his mother does not wish to breastfeed. Which of the following would be the *most appropriate* choice for this infant?

   A. Similac Pro-Advance® 20

   B. Enfamil® Enfacare®

C. Similac® Special Care® 24

D. Neocate® Synveo® Infant

3. A 3-month-old who was transitioned from breastfeeding to Gerber Good Start® Soothe is brought to clinic by the father who reports bloody stools for the past 2 days. The child otherwise looks healthy and has been gaining weight appropriately. The provider suspects cow milk protein allergy. Which of the following infant formulas would be the *most appropriate* option for this infant?

A. Similac® Neosure®

B. Similac® PM 60/40

C. Monogen®

D. Gerber® Good Start® Extensive HA®

4. A 2-month-old, term infantunderwent cardiothoracic surgery to repair a congenital heart defect. One week after restarting feeds with human milk, a pleural effusion was seen on the morning chest X-ray. The infant was diagnosed with a chylothorax. Initially, parenteral nutrition was used for 4 weeks, but enteral feedings will be started today. Which of the following would be the *bes*t formula choice for this infant?

A. Nutramigen® Enflora™ LGG®

B. Neocate® Infant DHA/ARA

C. Enfaport™

D. Alfamino® Infant

5. A mother in the United States with which of the following would be discouraged from either breastfeeding or using expressed milk to feed her infant?

A. Active tuberculosis; receiving treatment for 5 days

B. HIV, receiving antiretroviral therapy and a low viral load

C. Varicella; onset of symptoms 3 days prior to delivery

D. H1N1 influenza, receiving no treatment

6. Which of the following is correct information about human milk storage that should be provided to a breastfeeding mother who is taking her newborn home from the hospital?

A. When expressed milk is offered to the infant in a bottle immediately after pumping, any remaining may be refrigerated and used for the next feeding, if within 4 hours.

B. Fresh human milk may remain at room temperature for up to 12 hours.

C. Expressed human milk may be refrigerated for up to 2 weeks.

D. Expressed human milk can be kept in a deep freezer for up to 24 months.

7. A 6-year-old child (weight, 20 kg) is brought to the emergency department with a 2-day history of diarrhea with vomiting. The child has not been drinking well over the past 12 hours, and the parents were concerned for dehydration. The emergency physician confirms mild dehydration and recommends a trial of oral rehydration therapy (ORT). Per WHO guidelines, which of the following is the *most appropriate* volume and administration recommendations for ORS during the first 4 hours?

A. 2,000 mL at a rate of 200 mL every 5 minutes

B. 2,000 mL at a rate of 20 mL every 2-5 minutes

C. 1,000 mL at a rate of at least 50 mL every 15 minutes

D. 1,000 mL at a rate of at least 20 mL every 5 minutes

8. A 3-week-old term infant is being seen in clinic today for the first well-baby visit. The infant is being exclusively breastfed. The parents state that the infant is receiving no medications or supplements. Which of the following is the *best* recommendation for this infant?

A. No additional medications or supplements are needed now; return to clinic in 1 month.

B. Start vitamin D (ergocalciferol) 400 international units and iron sulfate 2 mg/kg elemental iron daily.

C. Start vitamin D (ergocalciferol) 400 international units daily.

D. Start iron sulfate 2 mg/kg elemental iron daily.

9. Infants may need more concentrated formulas (higher than the standard 20 kcal/oz [2.8 kJ/mL]) for a variety of reasons. Infant formulas can be reconstituted with less water to increase the caloric concentration. When concentrating a powder or concentrate formula by adding less water, what is the generally accepted *maximum* concentration recommended?

A. 22 kcal/ounce (3.1 kJ/mL)

B. 24 kcal/ounce (3.4 kJ/mL)

C. 27 kcal/ounce (3.8 kJ/mL)

D. 30 kcal/ounce (4.2 kJ/mL)

10. Severe food allergies require the use of a specialized infant formula. Which of the following is the formula of choice for a 5-month-old infant with severe food allergies?

A. Similac® Alimentum®

B. Monogen®

C. Pregestimil®

D. PurAmino®

11. A 10-year-old boy (weight, 35 kg) is in the PICU after suffering a burn in a motor vehicle accident. He has a transpyloric feeding tube with the tip in the jejunum. He suffered no injuries to his gastrointestinal tract. The burn team requests a high protein formula to begin tube feedings. Which of the following would be the *best* formula for this child?

A. Peptamen Junior®

B. Nutren Junior®

C. Peptamen Junior® HP

D. Pediasure® 1.5 Cal

12. Which of the following modular additives provides a source of both carbohydrate and fat?

A. Duocal®

B. Microlipid®

C. MCT Oil®

D. Polycose®

13. Which of the following would be the *most appropriate* initial formula for a premature infant with severe short bowel syndrome for whom human milk is not available?

A. Enfamil® AR

B. Similac® Special Care® 24

C. Enfamil® Enfacare®

D. Elecare®

14. Which of the following benefits has been associated with exclusive breastfeeding in infants?

A. Increased risk of obesity in later life

B. Increased risk of childhood leukemia

C. Decreased intelligence quotient (IQ) at 12 months of age

D. Decreased risk of viral gastroenteritis in infancy

15. Which of the following is a potential effect of lutein justifying its addition to infant formulas?

A. Improved neurodevelopment leading to better memory

B. Better calcium and phosphorus bone deposition that improves bone mineralization

C. More rapid maturation of the immune system

D. Improved visual acuity and protection from blue light

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Infants with galactosemia should not ingest lactose or galactose. Similac Pro-Total Comfort® 20 is lactose- and galactose-free; therefore, safe for this infant's nutrition. Human milk is high in lactose and maternal dietary changes cannot eliminate lactose from the infant's diet, so breastfeeding is contraindicated in this infant. Enfamil® NeuroPro™ Infant is a cow milk-based product which contains lactose. Enfamil NeuroPro™ Gentlease® has less lactose than standard cow milk-based infant formulas but still contains lactose.

2. **A.** Similac Pro-Advance® 20 is an appropriate infant formula for a healthy, near-term infant who is not being breastfed. Enfamil® Enfacare® is a post-discharge formula for premature infants going home from the hospital and the nutrient composition is not appropriate for a term infant. Similac® Special Care® 24 is a premature infant formula for low-birth-weight premature infants and not indicated in a healthy 36- week gestation infant. Neocate® Synveo® Infant is an amino acid-based infant formula indicated for children with various conditions that require a hypoallergenic or predigested formula.

3. **D.** Gerber® Good Start® Extensive HA® is an extensively hydrolyzed protein infant formula which can be used for infants with cow milk protein

allergy. Similac® PM 60/40 is a cow milk-based formula with low calcium and other alterations in mineral content for patients with hypercalcemia. Similac® Neosure® is a transitional formula for premature infants after they reach ~1.8 kg to 2 kg. It contains cow milk protein and would be unsuitable for this infant. Monogen® is a high medium chain triglyceride (MCT)-containing formula, which is derived from cow milk, so not suitable for this infant.

4. **C.** Infants with chylothorax should be initiated on a high MCT formula like Enfaport™. Limiting the long chain fatty acids ingested will help to diminish flow through the lymphatic system allowing time for the leak to fully heal. Nutramigen® Enflora™ LGG® (10%), Neocate® Infant DHA/ARA (8%), and Alfamino® Infant (43%) all contain some MCT; however, it is not enough for an infant with a chylothorax.

5. **B.** In the United States, mothers with HIV infection, irrespective of treatment status, are encouraged to not give their infants their breast milk either directly through nursing or by expressing a feeding with a bottle. Mothers with active tuberculosis, varicella, and H1N1 influenza should be physically separated from their infants until a specific amount of time for each condition has passed, but they may express milk and have someone feed it to their infant using a bottle.

6. **A.** Fresh expressed milk can be offered to a infant in a bottle, then the remaining can be placed in the refrigerator and used for the next feeding (within 4 hours). Since newborns eat every 2 to 3 hours, this is the best answer. Fresh expressed human milk should remain at room temperature for a maximum of 8 hours (4 hours is best). Human milk should remain refrigerated for no more than 8 days and frozen in a deep freezer for no more than 12 months.

7. **D.** For mild dehydration, the WHO guidelines for ORT recommend 50 mL/kg (1,000 mL) over the first 4 hours, trying to get the child to take at least 1 mL/kg (20 mL) every 2-5 minutes with a syringe, teaspoon, or medicine cup. A higher volume (50 mL, 2.5 mL/kg) may not be tolerated in a child with emesis. For moderate dehydration, the desired volume is 100 mL/kg (2,000 mL) with the same caveat about administering small volumes at a time.

8. **C.** Human milk is low in vitamin D content. The American Academy of Pediatrics and the World Health Organization recommend that infants who are exclusively breastfed receive a vitamin D supplement at a daily dosage of 400 international units, so this infant should be started on a vitamin D supplement. A term infant is born with adequate iron stores so that iron supplementation is not required until 4 months of age.

9. **C.** When concentrating infant formula with less water, each of the nutrients is provided in a greater concentration than if providing the standard 20 kcal/ounce (2.8 kJ/mL) formula. Therefore, unless under the direction of a nutrition specialist, infant formula should not be concentrated to a concentration higher than 27 kcal/ounce (3.8 kJ/mL).

10. **D.** Infants with severe food allergies will require a hypoallergenic, free amino acid-based formula such as PurAmino®. Similac® Alimentum® is a partially hydrolyzed formula and may be used for cow milk protein allergy in some infants but is not a free amino acid-based product and cannot be used for an infant with severe food allergies. Monogen® contains a higher proportion of calories from medium chain triglycerides but has intact protein; thus, it is unsuitable for this infant. Pregestimil® is an extensively hydrolyzed infant formula but is not a free amino acid formula.

11. **C.** Peptamen Junior® HP has a higher percentage of the calories from protein and would be most appropriate for this patient. Peptamen Junior®, Nutren Junior®, and Pediasure® 1.5 Cal are all formulas that are appropriate for a 10-year-old child, but they are not high-protein formulas.

12. **A.** The modular additive, Duocal®, contains both fat and carbohydrate. Microlipid® and MCT Oil® are modulars that provide additional calories from fat. Polycose® is a source of glucose polymers.

13. **D.** An infant with severe short bowel syndrome will require a hydrolyzed protein formula to allow for improved absorption. Of the formulas listed, Elecare® is the only one that is hydrolyzed and would be appropriate for an infant with short bowel syndrome. Enfamil® AR is a polymeric formula with added rice for infants with gastroesophageal reflux. It is contraindicated in preterm infants. Similac® Special Care® 24 is a premature infant formula, but it is not suitable for an infant with malabsorption. Enfamil® Enfacare® is also a polymeric formula used for premature infants during the transition from the hospital to home; it is not suitable for an infant with short bowel syndrome.

14. **D.** Human milk contains immunoglobulins from the mother that are transmitted to the infant. Breastfed infants have a decreased incidence of viral gastroenteritis compared to their formula-fed peers. Human milk has many beneficial effects for the infant including a decreased risk of obesity

and childhood leukemia as well as higher IQ scores in later life.

15. **D.** Lutein has significant effects in the eye, particularly protection against damage from blue light exposure. Other additives such as docosahexaenoic acid (DHA) are more associated with improved neurodevelopment. Additives such as lactoferrin are associated with immune function. None of the current formula non-nutrient additives improves bone mineralization.

Chapter e22: Pediatrics: Neonatal Critical Care

Kirsten H. Ohler; Jennifer T. Pham

KEY CONCEPTS

KEY CONCEPTS

① Pharmacokinetic parameters are altered across the age spectrum of the neonatal population (ie, preterm to term) because of developmental maturation and the effect of various disease states on these processes. Therefore, medication selection and monitoring is of utmost importance in this population.

② Treatment guidelines for neonatal resuscitation have been extrapolated from studies in older children and adults, which may not be optimal because of differences in the pathophysiology of cardiopulmonary arrest among these populations.

③ Neonatal sepsis can be categorized as either early-onset sepsis (EOS) or late-onset sepsis (LOS). Pathogens associated with neonatal sepsis vary depending on the onset of sepsis (EOS vs LOS).

④ Empiric antibiotic therapy should be initiated in infants with suspected sepsis and should target the most common pathogens.

⑤ Patent ductus arteriosus occurs commonly in preterm neonates and, if hemodynamically significant, requires pharmacologic (with a cyclooxygenase inhibitor) or surgical closure.

⑥ In certain congenital heart defects (eg, tetralogy of Fallot, hypoplastic left heart syndrome, transposition of the great arteries), it is imperative that the ductus arteriosus remains patent. Prostaglandin E1 (alprostadil) is the drug of choice in these cases.

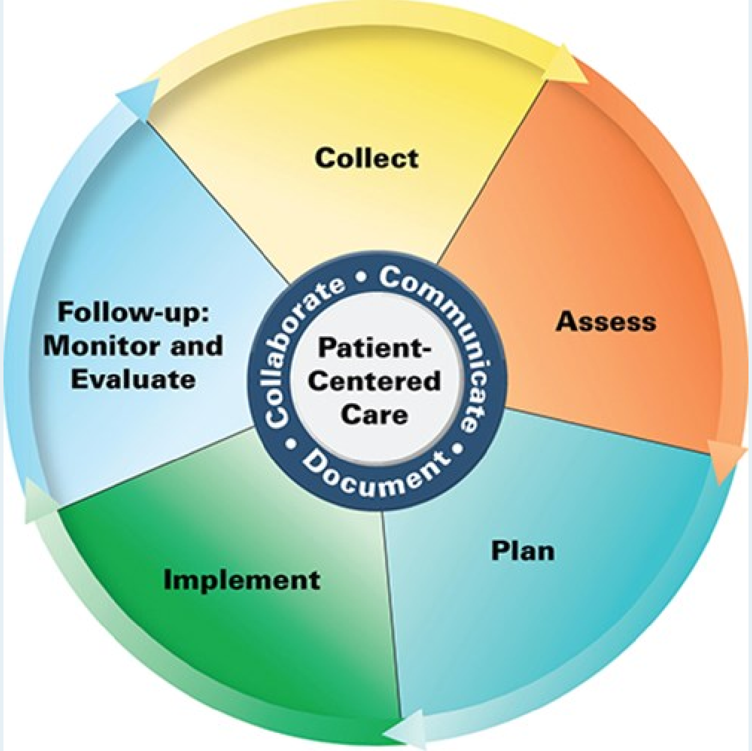
⑦ Neonatal hypotension can result in impaired cerebral perfusion and ischemic damage if left untreated. Since there is no clear consensus on the definition of neonatal hypotension, diagnosis and treatment are guided by clinical judgement, and review of the physiological parameters of the infant.

⑧ Pharmacologic therapy should be selected based on the etiology of hemodynamic instability and may include fluid bolus, vasopressors (eg, dopamine, dobutamine, epinephrine, norepinephrine), hydrocortisone, and vasopressin. Dopamine is the preferred initial vasopressor agent for hemodynamic support in neonates with hypotension.

⑨ Assessment of the degree of pain and sedation in the preverbal neonatal population is difficult. When using assessment tools, recognize the population and pain type for which each tool has been validated.

⑩ Opioids and benzodiazepines are commonly used to provide analgesia and sedation for critically ill neonates; however, there are concerns about their effects on long-term neurodevelopment.

Patient Care Process* for Neonatal Critical Care



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, gestational age, postnatal age [PNA]; see Table e22-1)
- Birth history (eg, ultrasound findings, timing of rupture of membranes, presence of maternal fever, Apgar scores, prenatal betamethasone, antibiotic therapy)
- Maternal history (eg, disease states, medications during pregnancy including substances of misuse)
- Current medications including surfactant, antibiotics, intravenous (IV) fluids, and parenteral nutrition (PN) orders
- Objective data
  - ◦ Blood pressure (BP), heart rate (HR), respiratory rate (RR), length, weight, oxygen saturation
  - ◦ Labs including electrolytes, blood urea nitrogen (BUN), serum creatinine (SCr), C-reactive protein (CRP), white blood cell count (WBC) and differential, cultures
  - ◦ Maternal serologies (eg, Group B streptococcus, hepatitis B, syphilis, HIV)

Assess

- Hemodynamic stability (see Table e22-5), evidence of peripheral perfusion (eg, capillary refill, peripheral pulses)
- Respiratory status (eg, grunting, flaring, retractions, need for respiratory support)
- Kidney function (eg, urine output, BUN, SCr)
- Pain (see Table e22-7)

Plan*

- Pharmacotherapeutic regimen including specific medication(s), route, dose, and frequency based on developmental pharmacokinetics
- Monitoring parameters using age-specific normal ranges
- Patient caregiver education (eg, purpose of treatment, medication administration/oral syringe technique, poison prevention principles)

Implement*

- Provide patient caregiver education regarding all elements of treatment plan
- Utilize technology (eg, "smart" IV pumps, computer order entry and dose range checking) to minimize medication errors

Follow-up: Monitor and Evaluate

- Re-evaluate weight-based and age-based medication dosing at least weekly
- Presence of adverse medication reactions

** Collaborate with patient's caregivers and other health professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video titled "Healthcare Heroes-NICU episode" at https://www.youtube.com/watch?v=DEheE4rr1GU. This 8-minute video provides a brief overview of the initial assessment and treatment of a critically ill neonate admitted to the neonatal intensive care unit (NICU). The video will enhance the student's understanding of the role of an interprofessional team in the complex care of an NICU patient. After watching the video, the student's reflection should include identification of the roles various healthcare providers (eg, pharmacist, nurse, nurse practitioner, respiratory therapist) can play in the management of an unstable neonate. The ASSESS and PLAN steps of the patient care process will be developed through this exercise.

INTRODUCTION

Healthcare providers working in the neonatal intensive care unit (NICU) care for a wide range of patients-from those born prematurely to term newborns, newly born infants to infants who have spent months to years in the NICU, those with acute illnesses to those with chronic morbidities associated with prematurity. A large proportion of NICU patients are born prematurely. In the United States, almost 1 in 10 births is premature.[1] Preterm birth occurs when a neonate is born before 37 completed weeks of gestation.[2] Prematurity can be further categorized as late preterm (ie, 34-37 weeks), moderate preterm (ie, 32-34 weeks), very preterm (ie, 28-32 weeks), and extremely preterm (ie, less than 28 weeks).[2] Neonates born prematurely can have multiple complications including respiratory distress syndrome, intraventricular hemorrhage (IVH), seizures, necrotizing enterocolitis (NEC), and sepsis, among others. Survivors of preterm birth often have morbidities such as bronchopulmonary dysplasia (BPD), neurodevelopmental delay, and cerebral palsy.[1,3] Despite medical advances, mortality in this population, especially those born extremely premature, remains high (30%-50%).[3]

① Opportunities abound to participate in the care of this heterogeneous NICU patient population. As such, there is terminology unique to the neonatal population that must be understood (Table e22-1). As a member of the interprofessional NICU team, the pharmacist has a key role in selection, dosing, and monitoring of medication therapy which is complicated by developmental pharmacokinetic changes that occur as a neonate ages from extreme prematurity to term (see Chapter e20). Neonates are rarely subjects in large, randomized, placebo-controlled clinical trials. Thus, only slightly more than 30% of the medications most commonly used in the NICU have an FDA-approved indication in neonates.[4] Because of differences in physiology and pharmacokinetics, as well as the developmental changes that occur in both of these over time, it is difficult and often inappropriate to extrapolate data from studies conducted in other patient populations to the care of a NICU patient. Clinical decisions are made based on small, retrospective studies; case reports; or past experience. Study enrollment may be limited by institutional review board (IRB) regulations for conducting research in this vulnerable population as well as parents' reluctance to enroll their newborn in a clinical trial.[5,6]

TABLE e22-1

Neonatal Terminology

Term	Definition
Gestational age (GA)	Time between first day of mother's last menstrual period to the day of birth; reported as weeks plus days (eg, 32 4/7 weeks means the neonate was born at 32 weeks plus 4 days)
Postnatal age (PNA) or chronological age	Time since birth; reported as days (PNA), weeks, months, or years
Postmenstrual age (PMA)	GA plus chronological age (eg, if 16-day-old infant was born at 28 2/7 weeks then PMA is 30 4/7 weeks)
Very low birth weight (VLBW)	Birth weight (BW) less than or equal to 1,500 g
Extremely low birth weight (ELBW)	BW less than or equal to 1,000 g

Data from Reference 7.

Healthcare providers must prevent and identify medication errors because neonates represent a very high-risk population.[8] Medication errors occur most commonly in the neonatal population for various reasons, including developmental changes; a neonate's inability to communicate with the healthcare team; complex calculations required to determine doses; a lack of commercially available, age-appropriate dosage forms; and a paucity of robust, published drug information related to medication use in this population.[9]

NEONATAL CARDIOPULMONARY RESUSCITATION

② Resuscitation of a newborn in the delivery room may be necessary for various reasons including respiratory failure due to prematurity, a hypoxic-ischemic *in utero* event, and medication-induced respiratory depression. During the first minute after birth, the neonate's tone, RR (eg, presence of apnea) and pattern (eg, gasping, labored), cry, and HR are assessed. If any abnormalities are noted, positive pressure ventilation is initiated. The basis of neonatal resuscitation is inflation and ventilation of the lungs; unlike in adults, cardiopulmonary collapse is rarely caused by nonperfusing rhythms such as ventricular fibrillation.[10,11] If after 30 seconds of adequate ventilation and corrective measures (eg, positioning airway, clearing secretions, intubation) the HR remains or falls below 60 bpm, chest compressions are initiated in the neonate.[12,13] This is different than adult life support during which chest compressions begin when a pulse cannot be detected.[14] If the newborn's HR remains below 60 bpm after 30 seconds of effective chest compressions, epinephrine is indicated.[12,13] The majority of newborns will not require epinephrine administration; less than 0.1% receive epinephrine despite requiring cardiorespiratory support in the delivery room.[15]

If epinephrine is indicated, it is preferred to be given by the IV route.[12] A catheter is often placed in the umbilical vein to establish IV access during newborn resuscitation.[11,16] The optimal dose of epinephrine during resuscitation has not been studied in neonates so the recommended dose, 0.01 to 0.03 mg/kg/dose, has been extrapolated from adult data.[12,17] If IV access cannot be established, epinephrine can be administered by an endotracheal tube (0.05-0.1 mg/kg/dose).[12] Although epinephrine administration by the endotracheal tube is often done because the route is readily accessible, the efficacy is less than when administered intravenously.[16] The difference in efficacy may be because endotracheal administration results in lower peak and overall plasma concentrations of epinephrine compared to IV administration despite higher doses.[18–20] The difference in efficacy may be further magnified in newborns because of medication dilution in retained fetal lung fluid immediately after birth.[11] Systemic absorption of epinephrine from the lungs may also be decreased in the newborn because of right-to-left shunting of blood (ie, from the pulmonary artery to the aorta) through the patent ductus arteriosus (PDA) resulting in reduced blood flow to the pulmonary circulation.[11] The intraosseous (IO) route, which is a preferred route in pediatric advanced life support (PALS), is also an alternative if IV access cannot be established in a newborn, although establishing this form of access is not generally done in preterm neonates.[21,22]

Alternatives to standard-dose epinephrine have been evaluated. Higher dose IV epinephrine (0.05-0.2 mg/kg) does not appreciably improve outcomes and in cases of arrest precipitated by asphyxia, survival is worse when high-dose epinephrine is used.[23–26] This finding is relevant because most newborn cases are associated with hypoxia and asphyxia. Another concern related to the use of high-dose epinephrine is abrupt rebound hypertension. This acute fluctuation in BP could increase the risk of IVH particularly in premature neonates undergoing cardiopulmonary resuscitation (CPR).[10,21,27] Vasopressin is another alternative to epinephrine and provides the advantage of not increasing myocardial oxygen demand, but there is no evidence to support its use in pediatric or neonatal resuscitation.[10,21,28]

Sodium bicarbonate was routinely administered during neonatal resuscitation to treat the mixed respiratory and metabolic acidosis that results from failure of the cardiopulmonary system. This practice has fallen out of favor because of concerns about the potential to worsen myocardial function and respiratory acidosis because of carbon dioxide production and increase the risk of IVH because of its hyperosmolarity. Additionally, sodium bicarbonate use does not improve neurodevelopmental outcomes or survival following resuscitation. Administration of sodium bicarbonate may still be considered during prolonged resuscitation efforts if metabolic acidosis persists despite adequate ventilation and perfusion.[27]

Historically, naloxone was given to newborns experiencing respiratory depression in the delivery room because of maternal opioid exposure during labor. However, naloxone administration does not decrease the need for assisted ventilation in the delivery room or admissions to the NICU.[29] Withdrawal symptoms have been precipitated by naloxone administration in neonates born to mothers with opioid use disorder.[30] Because of lack of evidence for benefit and the potential for harm, naloxone use is not recommended in cases of neonatal respiratory depression immediately after birth in the setting of maternal opioid administration; instead the newborn should be supported with positive pressure ventilation.[13]

Mortality following newborn resuscitation is between 10% and 30%.[31] Extremely low-birth-weight neonates who receive CPR in the delivery room have a higher mortality rate (70%) and survivors are more likely to develop severe IVH and BPD. Additionally, the incidence (50%-90%) of neurodevelopmental impairment (eg, cerebral palsy, deafness) and death is higher in these patients than those who do not require resuscitation.[28,32,33]

NEONATAL SEPSIS AND MENINGITIS

Epidemiology

③ Neonatal sepsis and meningitis contribute to neonatal morbidity and mortality. Neonatal sepsis can be categorized as either early-onset sepsis (EOS) or late-onset sepsis (LOS), depending on the age at onset of signs and symptoms. Early-onset sepsis is defined as a positive blood or cerebrospinal fluid (CSF) bacterial culture within 72 hours of life compared to greater than 72 hours of life for LOS. The overall incidence of EOS is about 1.08 cases per 1,000 live births in the United States and is inversely proportional to birth weight (BW) and gestational age (GA).[34] The incidence of EOS is about 18.5 cases per 1,000 infants born at 22 to 28 weeks' gestation; 6.2 per 1,000 infants born at 29 to 33 weeks' gestation; 0.73 per 1,000 infants born at 34 to 36 34 weeks' gestation; and 0.56 per 1,000 infants born at 37 weeks' gestation or greater.[34,35] Similar to EOS, the incidence of LOS is also inversely related to BW and GA, with an incidence of 51% in those with BW 501 to 750 g compared to 16.3% in those with BW 1,001 to 1,250 g and 7.5% in those with BW 1,251 to 1,500 g.[36] Risk factors for neonatal sepsis include prematurity, male sex, African-American descent, and predisposing maternal conditions such as chorioamnionitis, prolonged rupture of membrane, and urinary tract infection.[37] Premature infants have a 3 to 10 times higher incidence of neonatal sepsis than full-term infants due to their lower immunoglobulin concentrations and decreased neutrophil function. The incidence of mortality from neonatal sepsis is also inversely related to GA: 50% in those born at 22 to 24 weeks' gestation compared to 30% at 25 to 28 weeks' gestation, 12% at 29 to 33 weeks' gestation, and 1.6% at ≥ 37 weeks' gestation.[35,37]

Common Pathogens

Early-Onset Sepsis

Early-onset sepsis occurs in utero and is acquired either transplacentally or via ascending bacteria entering the uterus from the vaginal environment following a ruptured amniotic membrane. Once the membranes are ruptured, the infant may be at risk for colonization of microorganisms from the maternal genital tract. It can also occur when infants are exposed to pathogenic bacteria, viruses, or fungi while passing through the birth canal. Risk factors for EOS include the presence of chorioamnionitis, prolonged rupture of membranes, vaginal colonization with group B *Streptococcus* (GBS), GBS bacteriuria, and prematurity. The most common pathogens for EOS are *Escherichia coli* (36.6%) and GBS, also known as *Streptococcus agalactiae* (30.2%).[34] Other pathogens include *Listeria monocytogenes*, other streptococci (most commonly viridans group streptococci), *Enterococcus* species, nontypeable *Haemophilus influenzae*, and *Candida* species. GBS infections usually occur in term infants, whereas *E. coli* is more common among preterm infants, both at 52%.[34] *Listeria* is usually acquired via maternal consumption of contaminated meats, poultry, and dairy products.

Late-Onset Sepsis

Late-onset infections are acquired after delivery or beyond 3 to 7 days of age and are attributed to organisms acquired from the hospital or community environment. Neonates with central venous catheters are at higher risk for LOS. Other risk factors include prematurity, low BW, PN, prolonged hospitalization, prior antibiotic use, use of histamine (H_2)-receptor blockers, and NEC. Late-onset sepsis is usually caused by the same organisms as for EOS or by nosocomial pathogens. Gram-positive organisms constitute 79%, with coagulase-negative staphylococci (CONS; specifically, *Staphylococcus epidermidis*) occurring in 57% of the total and *S. aureus* in 12%. Gram-negative organisms such as *Enterobacteriaceae* and *Pseudomonas* species constitute 19% of the total, with *E. Coli* being the most predominant (7% of total).[38] Although CONS are the most commonly isolated pathogens in neonates with LOS), especially among those with central venous catheters, it is important to distinguish whether the presence of CONS is the result of colonization of IV catheters or represents a true bacteremia.

Viral infections, such as herpes simplex virus (HSV) and enteroviruses, can also cause EOS and meningitis, but are more common in LOS. About 5% of neonatal HSV infections are acquired in utero, 85% are peripartum, and 10% are postnatally.[39] HSV infections are associated with high morbidity and mortality and are usually due to HSV-1 infection. In addition to bacterial and viral infections, fungal pathogens can cause neonatal sepsis (more commonly associated with LOS) and are inversely related to GA and BW. The incidence of invasive candidiasis varies but can be as high as 10% to 16% in ELBW infants compared to 2% to 8% in VLBW infants.[40] In addition, *Candida* species colonization can be as high as 60% in VLBW with up to 20% progressing to invasive fungal infections.[40] Risk factors include extreme prematurity, abdominal surgery, central venous catheters, prolonged use or broad-spectrum antibiotics, steroids and H_2 blockers, and prolonged duration of mechanical ventilation.

Meningitis should always be considered in infants with neonatal sepsis. Although the incidence of neonatal meningitis is low, it remains a devastating infection with high morbidity and mortality. The pathogens causing neonatal meningitis are the same as for neonatal sepsis. Neonatal meningitis is often caused by GBS (50%) followed by *E. Coli* (20%). *Citrobacter* species and *Cronobacter sakasakii*, although uncommon (~5% in VLBW infants), are important pathogens due to their association with meningitis from brain abscesses.[34,41] Most cases of meningitis are late-onset infections resulting from hematogenous spread.

Clinical Presentation

The clinical signs and symptoms of neonatal sepsis and meningitis vary by GA and severity of infection, ranging from nonspecific to multiorgan failure. Initially, infants with neonatal sepsis may have poor feeding, irritability, lethargy, and hypothermia. Fever is uncommon unless the infants are born to a febrile mother and have a fever immediately after delivery. In addition, infants with neonatal sepsis can have respiratory (eg, apnea, tachypnea, grunting, nasal flaring) or cardiac symptoms (eg, cyanosis, desaturation, bradycardia, poor perfusion, metabolic acidosis, hypotension). Premature infants usually present with apnea, bradycardia, cyanosis, and lethargy while term infants will present with respiratory distress. Late complications of neonatal infection include jaundice, hepatosplenomegaly, respiratory failure, severe metabolic acidosis, bone marrow dysfunction (eg, neutropenia, thrombocytopenia), and disseminated intravascular coagulation.[37] Most infants with EOS will present within the first 24 to 48 hours of life, and those with gram-negative and fungal infections will have more severe symptoms than those with gram-positive infections. It is important to perform a thorough review of antenatal risk factors when evaluating an infant for suspected sepsis and meningitis. The presence of rash, seizures, or liver dysfunction should lead to suspicion of a viral infection such as HSV.[39]

Diagnostic and Laboratory Findings

A complete sepsis workup for neonatal sepsis includes a blood culture, complete white blood cell count (WBC) with differential, a urine culture (for LOS only), and a lumbar puncture (LP) for cell count and culture. The gold standard for diagnosis of neonatal sepsis is the isolation of an organism in blood culture. A minimum of 1 mL of blood, collected from a peripheral vein, is recommended for blood cultures for EOS.[42] For LOS, two different venipunctures (1 mL of blood) from two separate sites for blood cultures are required. This is particularly important for those with central venous catheters, since a true pathogen is more likely to be present in both culture specimens. This will identify those with a true bacterial infection versus those with colonization. Because of a decreased detection of organisms due to the small amount of blood obtained for blood cultures, neonatal sepsis cannot be excluded when blood cultures show no growth. WBC with differential and the ratio of immature to total neutrophils (I/T) are commonly used as screening tests for neonatal sepsis. An I/T ratio is defined as immature (bands plus earlier cell lines) to total neutrophils (neutrophils plus immature cells); a ratio of less than 0.2 is considered normal. Unfortunately, none of these tests are absolutely indicative of neonatal sepsis as they have poor sensitivity and specificity. Neutropenia has a greater specificity and can be a sign of WBC depletion from bone marrow owing to overwhelming sepsis. An elevated WBC can also indicate bacterial infection but may be less specific. In contrast, those with viral infections, including HSV, usually have normal WBC. Leukopenia, neutropenia, and elevated I/T ratio were associated with increased odds of infection, with high specificity and negative predictive value and low sensitivity.[43]

Generally, a urine culture is not needed for neonates suspected of EOS since most urinary tract infections in neonates are secondary to seeding of bacteria in the kidney. However, urine culture is routinely performed in neonates suspected with LOS. Specimens should be obtained only by suprapubic aspiration or urethral catheterization since there is a higher risk of bacterial contamination with bag urine specimens and neonates are unable to provide a clean catch urine. A LP should be performed in neonates with a positive blood culture, abnormal neurologic signs, or elevated WBC or left shift. CSF cultures may be falsely negative in those who are receiving antibiotic therapy prior to an LP. Therefore, it is important to not only send CSF fluid for culture but for cell counts with differential, glucose, and protein concentrations. Although a CSF WBC count < 20 cells/mm^3 (0.02 x 10^9/L) is considered normal in most infants, the levels are age-dependent, with the highest levels occurring in the first week of life.

C-reactive protein (CRP) and procalcitonin (PCT) are commonly evaluated acute-phase reactants in the diagnosis of neonatal sepsis. A CRP concentration of greater than 10 mcg/mL (mg/L) is frequently used as a cut-off for normal. CRP concentrations rise within 6 to 8 hours and peak at 36 to 48 hours. Due to the delayed response, CRP may not be useful for detection of EOS. It has a sensitivity of 30% to 80% and a specificity of 83% to 100% as a marker for bacterial infection.[43] Two or more normal CRP concentrations indicate that sepsis is unlikely and antibiotic therapy can be discontinued.[38,43] In contrast, elevated CRP concentrations do not always indicate bacterial infection since other clinical conditions such as chorioamnionitis, meconium aspiration syndrome, surfactant administration, viral infection, hemolysis, and ischemic tissue injuries can result in elevated CRP concentrations.[43] Therefore, serial CRP concentrations may be used to assess clinical improvement and guide duration of antibiotic therapy. Assays for CRP measurement are reliable, rapid, and inexpensive. CRP is most commonly evaluated in the diagnosis of neonatal sepsis, mainly because it is more studied for neonatal sepsis and reference ranges for neonates are established.

Procalcitonin, a precursor protein of calcitonin, is another acute-phase reactant protein that may be more useful for early detection of sepsis since it is released (3-4 hours) and peaks (6-24 hours) earlier than CRP in the presence of bacteria. It has a sensitivity of 92% and specificity of 97% for early diagnosis of EOS.[43] However, its use may be limited due to the lack of age-specific reference ranges; although in most cases, the normal concentration for neonates >72 hours of age is usually <0.1 mcg/mL (mg/L). In addition, PCT plasma concentrations may be influenced by prematurity, intracranial hemorrhage, birth depression, chorioamnionitis, prolonged rupture of membranes ≥ 18 hours, surfactant administration, and pre- and postnatal use of antibiotics.[43] Furthermore, the methods used to measure PCT concentrations are costly.

Because laboratory markers and clinical signs and symptoms are nonspecific in neonates, the Kaiser neonatal sepsis calculator was developed.[44] This calculator is used to assess the need for antibiotic therapy and laboratory monitoring for EOS in infants ≥ 34 weeks' gestation based on maternal risk factors as well as the infant's clinical examination. Use of the neonatal sepsis calculator reduces antibiotic use and hospitalization as well as the need for blood culture evaluation; however, there is no difference in mortality, culture-positive EOS, and hospital readmissions.[45] This tool is not validated for use in preterm infants < 34 weeks' gestation and does not guide the duration of antibiotic therapy for EOS.

Treatment

Empiric Antibiotic Therapy for EOS

④ Empiric antibiotics should be initiated in infants with suspected sepsis once a blood culture is obtained and should target the most common pathogens. Delaying antibiotic initiation may result in high morbidity and mortality. The combination of ampicillin and an aminoglycoside (eg, gentamicin, tobramycin) is commonly initiated for EOS.[35] This combination covers *E. coli* and has synergistic activity against GBS and *L. monocytogenes*. In addition, these antibiotics are bactericidal against the common neonatal pathogens, penetrate into the CNS, and are generally effective and safe. Meningitic doses of ampicillin, which are higher than those used for other infections, should be used until meningitis is ruled out. Selection of a specific aminoglycoside should be determined by a NICU-specific antibiogram. Amikacin is generally reserved for gram-negative organisms resistant to gentamicin or tobramycin. When dosing aminoglycosides, it is important to select a dosing regimen that is safe and achieves therapeutic serum concentrations, with peak concentrations at least 8 to 10 times greater than the minimum inhibitory concentration (MIC) of the organism being treated and low trough concentrations (< 1 μg/mL [mg/L]).

Traditional dosing of aminoglycosides was 2.5 mg/kg/dose every 8 hours. However, this dosing strategy resulted in subtherapeutic peak and supratherapeutic trough concentrations especially in preterm infants due to a higher volume of distribution and slower renal elimination of aminoglycosides, respectively. Most institutions utilize extended-interval dosing (EID) of aminoglycosides in neonates, where higher mg/kg doses (eg, 4-5 mg/kg/dose) are given at prolonged dosing intervals (eg, every 24, 36, or 48 hours, depending on PMA). EID of gentamicin achieves more therapeutic peak and trough concentrations without increasing nephrotoxicity and auditory toxicity compared with multiple daily dosing in both term and preterm neonates.[46,47] The rationale for EID dosing is to enhance bacterial killing by providing higher peak serum concentration to MIC ratio and minimizing postexposure microbial resistance by achieving a drug-free period at the end of the dosing interval.[46] For EID of aminoglycosides in neonates, peak concentrations are usually between 8 and 12 μg/mL (mg/L) while trough concentrations are usually low but detectable. Routine peak and trough concentrations are needed for neonates as there is no nomogram available to guide dosing adjustment. EID of aminoglycosides in neonates should not be confused with EID of aminoglycosides in adults which involves different dosing frequency and concentration targets.

Cefotaxime, a third-generation cephalosporin, may be added or used in place of gentamicin in infants suspected with gram-negative meningitis due to its greater CNS penetration compared with aminoglycosides. Other advantages of cefotaxime are that it is less nephrotoxic and does not require serum concentration measurements. However, its use has been associated with the development of resistant gram-negative bacilli such as *Enterobacter cloacae* and increased risks for invasive candidiasis, NEC, and death.[42] Therefore, cefotaxime should be reserved for neonates with suspected meningitis or those with aminoglycoside-resistant gram-negative bacilli; for those where serum gentamicin concentrations are not available at their institutions; and for those with impaired kidney function. Ceftriaxone, a highly protein-bound antibiotic, should not be used in neonates due to its risk of kernicterus secondary to displacement of bilirubin from albumin. Furthermore, biliary sludging may occur in neonates receiving ceftriaxone. In addition, concomitant ceftriaxone and calcium infusions may result in neonatal death. Calcium-ceftriaxone precipitates have been found in the lungs and kidneys of infants given calcium-containing products and ceftriaxone within 48 hours from each other.[48]

Due to the shortage of cefotaxime, ceftazidime has been used as an alternative as it offers the same coverage and is approved by the Food and Drug Administration for all pediatric patients. Ceftazidime achieves therapeutic concentrations in all tissues, including the CSF. Unlike cefotaxime, ceftazidime has not been used extensively in neonates; therefore, neonates should be closely monitored for efficacy and toxicity. Furthermore, it is important to monitor for potential bacterial resistance, as well as other potential risks such as invasive candidiasis, NEC, and death, all of which have been associated with cefotaxime in neonates.

Empiric Antibiotic Therapy for LOS

Initial empiric antibiotic therapy for LOS or meningitis should be directed toward common nosocomial pathogens as well as the primary pathogens for EOS. For many years, empiric antibiotic therapy included a combination of gentamicin and vancomycin since CONS is the most common causative organism. However, due to an increased emergence of vancomycin-resistant *Enterococcus* and *S. aureus*, the Centers for Disease Control and Prevention have recommended against using vancomycin empirically. Vancomycin should be used selectively in infants with proven CONS or methicillin-resistant *S. aureus* (MRSA) bacteremia. Institutional NICU guidelines should be implemented to guide selective use of vancomycin based on individual NICU's nosocomial pathogens and susceptibility patterns as well as patient risk factors, clinical condition, and previous antibiotic usage. Many neonatal centers are now using nafcillin or oxacillin in place of vancomycin to decrease vancomycin use and decrease vancomycin-resistant organisms. Patients with suspected HSV infection should be initiated with IV acyclovir. Treatment with IV acyclovir decreases mortality and morbidity in infants with CNS and disseminated disease. In those with skin, eye, and oral mucosal disease, IV acyclovir may also prevent progression to disseminated or CNS disease.[39] Antimicrobial dosing regimens for EOS and LOS are given in Tables e22-2 and e22-3.

TABLE e22-2

Antimicrobial Dosage Regimens for Neonates

	Chronologic Age ≤ 28 days				Chronologic Age > 28 days

	≥8	5 mg/kg/dose Q 24 hr

Data from References 49-51.

[a] Some institutions empirically adjust dosing interval based on clinical factors that may affect renal medication clearance (eg, birth depression, hypotension requiring vasopressor support, congenital heart defects resulting in decreased peripheral perfusion).

Based on Infectious Diseases Society of America guidelines, NICUs with high rates (> 10%) of invasive candidiasis should provide prophylactic fluconazole, given orally or intravenously, at a dose of 3 to 6 mg/kg/dose twice weekly for 6 weeks to all ELBW infants.[52] If fluconazole is not available or if there are concerns for resistance, oral nystatin at a dose of 100,000 units three times a day for 6 weeks can be used as an alternative in VLBW infants. Prophylactic fluconazole decreases invasive candidiasis, fungal colonization rate, and mortality in ELBW and VLBW infants. In addition, short-term use of prophylactic fluconazole does not result in the development of fungal resistance or significant adverse medication reactions.[40] Despite the benefits of prophylactic fluconazole, there is also a concern for the potential development of resistant pathogens as well as the adverse medication reactions of long-term use of fluconazole. Infants should be monitored for potential short- and long-term adverse medication reactions associated with fluconazole.

For systemic neonatal fungal infections, conventional amphotericin B deoxycholate is considered the empiric treatment of choice. Fluconazole may be considered as initial treatment in infants who have not received prophylactic fluconazole.[42] Liposomal amphotericin B may also be used as an alternative but not for the treatment of urinary tract infections due to its inadequate penetration in the kidneys. There is an increased rate of mortality associated with liposomal amphotericin treatment when compared to conventional amphotericin B or fluconazole.[53] Therefore, conventional amphotericin B and fluconazole remain the medications of choice for empiric therapy.

For both EOS and LOS, once a pathogen is isolated and antimicrobial susceptibilities are available, antibiotic therapy should be tailored accordingly. Blood, CSF, and/or urine cultures should be repeated after 24 to 48 hours of appropriate therapy to ensure bacterial elimination.

Duration of Therapy

Treatment duration for culture-proven sepsis varies from 10 to 14 days. For those with meningitis, the duration of therapy varies depending on the organisms. For gram-positive pathogens, infants should receive at least 14 days of therapy and 21 days for gram-negative pathogens. In general, antibiotic therapy should be continued for a minimum of 14 days after the repeat CSF culture is negative. Infants with abscesses, osteomyelitis, or endocarditis may require longer durations of therapy. Oftentimes, clinicians opt to continue antibiotic therapy up to 7 to 10 days in infants with culture-negative sepsis who is clinically septic or who may have abnormal laboratory tests. Cardiorespiratory instability in VLBW infants is common and should not justify the need for prolonged antibiotic therapy. Unnecessary and prolonged antibiotic therapy can lead to long-term complications. VLBW neonates exposed to prolonged antibiotic therapy within the 14 days of life are at an increased risk of the composive outcome of LOS, NEC, or death.[54] This may be because antibiotic therapy may promote dysbiosis of the gut, skin, and respiratory tract. Therefore, for those with negative cultures, antibiotic therapy should be discontinued by 36 to 48 hours.[35] Furthermore, abnormal laboratory tests should not be used solely to continue antibiotic therapy.[35] Clinicians should weigh the risk/benefit of continuing antibiotic therapy in those with culture-negative sepsis and discontinue therapy as soon as the patients are clinically improving, and laboratory markers are returning to normal.

Therapeutic Drug Monitoring

Aminoglycosides exert a concentration-dependent killing effect and may cause nephrotoxicity and ototoxicity. Therefore, therapeutic drug monitoring (TDM) is important to maximize efficacy while reducing toxicity. Most infants with suspected sepsis will be treated with gentamicin for 48 hours and, therefore, TDM of gentamicin is not necessary, especially if EID is utilized. However, if treatment is beyond 72 hours, gentamicin peak and trough concentrations should be obtained at steady-state conditions, prior to the second (if receiving every 36- to 48-hour dosing) or third (if receiving every 24 hour dosing) dose. In those with unstable kidney function, gentamicin concentrations should be obtained immediately, regardless of the number of doses administered. Serum trough concentrations should be obtained at least 30 minutes or immediately before the dose; serum peak concentrations should be obtained at least 30 to 60 minutes after the end of a 30-minute infusion. Therapeutic peak concentrations of 8 to 10 μg/mL (mg/L; 16.7-20.9 μmol/L) (for MIC ≤ 1) are generally targeted with trough concentrations < 1 μg/mL (mg/L; 2.1 μmol/L). Similar to gentamicin, vancomycin can also cause nephrotoxicity but exert a time-dependent killing. Therapeutic monitoring of vancomycin is warranted if treatment is beyond 48 hours. Due to increased risk of nephrotoxicity associated with vancomycin trough concentrations of 15 to 20 μg/mL (mg/L; 10.4-13.8 μmol/L), trough-only monitoring is no longer recommended in adult patients with serious infections (eg, bacteremia, endocarditis, osteomyelitis, meningitis, and pneumonia due to MRSA). An AUC/MIC of 400 to 600 mg·L/hr (MIC ≤ 1) is now recommended, as this achieves clinical efficacy while reducing nephrotoxicity in adult and pediatric patients, including neonates.[55] For pediatric and neonates, vancomycin exposure should be maintained below an AUC of 800 mg·L/hr and trough concentrations ≤ 15 μg/mL (mg/L; 10.4 μmol/L)(at least 30 minutes or immediately before the third or fourth dose) to minimize the risk for nephrotoxicity. Monitoring of peak vancomycin concentrations is not recommended. Obtaining targeted vancomycin trough concentrations in neonates remains controversial. Vancomycin trough concentrations as low as 7 μg/mL (mg/L; 4.8 μmol/L) can still achieve targeted AUC/MIC ≥400 mg·L/hr in neonates due to slower clearance.[55]

CONGENITAL HEART DEFECTS

Nearly 1% of all babies born in the United States each year have a congenital heart defect (CHD). These defects have a wide range of severity and are generally classified as cyanotic or acyanotic. They can also be classified as critical (ie, requiring surgery within the first year after birth) or noncritical. About 25% of CHDs are considered critical. Most children with noncritical CHD survive into adulthood, but only about 69% of those with critical CHD survive. More than half of the survivors of critical CHD will have developmental disabilities or delays.[56,57]

Acyanotic Heart Defects

Most acyanotic CHDs (eg, atrial septal defect, ventricular septal defect) do not require pharmacologic treatment in the immediate postnatal period. Depending on the size of the defect, some infants eventually will require treatment for heart failure symptoms, most commonly with diuretics, angiotensin-converting enzyme inhibitors, and digoxin, before surgical closure of the defect.[57] However, PDA is an acyanotic defect that frequently requires pharmacologic management in the NICU.

Patent Ductus Arteriosus

⑤ The ductus arteriosus is an essential fetal vessel that connects the pulmonary artery and descending aorta allowing oxygenated blood from the placental circulation to enter the fetal systemic circulation (Figure e22-1). In the fetus, pulmonary vascular resistance (PVR) is elevated causing blood to flow from the pulmonary artery to the aorta (ie, right-to-left shunt). The fetal ductus arteriosus remains patent due in part to high circulating concentrations of prostaglandins. After a full-term birth, a large drop in prostaglandin concentration occurs, which results in functional closure of the ductus arteriosus by about 24 hours after birth. In preterm neonates, several factors including (1) incomplete prostaglandin metabolism, (2) increased sensitivity to prostaglandins, (3) lower ductal tone, and (4) decreased muscle fibers within the ductus arteriosus contribute to the vessel remaining patent.[58,59] Approximately half of neonates born younger than 29 weeks' gestation will have a PDA.[59]

FIGURE e22-1

In normal fetal circulation, gas exchange occurs in the placenta from which oxygenated blood travels through the umbilical vein to the inferior vena cava. After entering the right atrium, a large portion of the blood is shunted across the foramen ovale to the left atrium where it is subsequently pumped into the systemic circulation via the left ventricle and aorta. Blood that enters the right ventricle is pumped into the pulmonary artery from which a large volume is shunted across the ductus arteriosus to the aorta and systemic circulation. The fetal lungs do not play a role in oxygenating blood.

Neonates with a PDA may be asymptomatic or have hemodynamic alterations depending on the size of the ductal lumen and the degree and direction of blood shunting across the PDA. After birth, PVR decreases and systemic vascular resistance (SVR) increases. This can result in blood flow from the aorta to the pulmonary artery (ie, left-to-right shunt). If the PDA is hemodynamically significant, the left-to-right shunt can cause decreased kidney, intestinal, and cerebral perfusion. Complications associated with altered systemic blood flow because of a PDA include acute kidney injury (AKI), NEC, and IVH. Additionally, overcirculation of pulmonary blood flow can result in pulmonary edema, pulmonary hemorrhage, BPD, and right heart failure.[59]

Controversy exists about what the optimal timing for PDA closure is and whether or not all patients with a PDA require medical closure (ie, pharmacological or surgical). If pharmacologic closure is planned, the preferred agents are the cyclooxygenase inhibitors (ie, indomethacin or ibuprofen). Three pharmacologic approaches have been assessed: prophylaxis (administered within 24 hours of birth), early (administered within 6 days after birth), or late symptomatic (administered 6 days or later after birth) treatment. Prophylaxis reduces hemodynamically significant PDA, need for surgical ligation, and IVH (specifically if indomethacin is used) without increasing bleeding or spontaneous intestinal perforation. The use of prophylactic indomethacin may decrease urine output. Because this approach has not improved neurodevelopmental outcomes or reduced BPD and it exposes neonates who may have spontaneous ductal closure to potential adverse medication reactions, routine prophylaxis is no longer common practice. Early treatment does not reduce BPD and also may treat neonates who would otherwise have spontaneous closure of their PDA. This approach is only recommended for neonates born before 28 weeks' gestation with a significant left-to-right shunt who require more than minimal respiratory support. Conservative management with fluid restriction and "watchful waiting" is recommended for those without hemodynamic alterations, with late treatment recommended if the PDA becomes hemodynamically significant.[58,59]

There is also controversy about the medication of choice for PDA closure (indomethacin vs ibuprofen). Indomethacin and ibuprofen have similar efficacy in closing the PDA (~70%-80%), but their dosing regimens differ. Indomethacin dosing is based on PNA (Table e22-4). Indomethacin decreases mesenteric blood flow to a greater degree than ibuprofen, so the risk of NEC and AKI is higher with indomethacin. However, more neonates exposed to ibuprofen develop BPD and, because ibuprofen is highly protein bound, the risk of kernicterus because of displacement of bilirubin from albumin binding sites in neonates with hyperbilirubinemia is a concern.[58,59] Because of its overall favorable safety profile, ibuprofen is often considered the medication of choice.[59]

TABLE e22-4

Medications Used for PDA Closure

Medication	Dosing Regimen	Monitoring Parameters
Indomethacin	• **IV, intermittent:** • PNA <48 hours: 0.1 mg/kg/dose Q 12-24 hours × 3 doses • PNA 2-7 days: 0.2 mg/kg/dose Q 12-24 hours × 3 doses • PNA >7 days: 0.25 mg/kg/dose Q 12-24 hours × 3 doses	• Urine output (hold dose if <0.6 mL/kg/hr), SCr (hold dose if >1.6 mg/dL [141 µmol/L]), platelets, signs of bleeding • BP, murmur, respiratory status, echocardiogram
Ibuprofen	• **IV, intermittent:** • "Standard-dose": 10 mg/kg/dose x 1 dose followed by 5 mg/kg/dose Q 24 hours × 2 doses • "High-dose": 20 mg/kg/dose × 1 dose followed by 10 mg/kg/dose Q 24 hours × 2 doses • *High-dose regimen found to have higher closure rates compared to standard-dose without more frequent adverse medication reactions	• Urine output (hold dose if <0.6 mL/kg/hr), serum creatinine, platelets, signs of bleeding • BP, murmur, respiratory status, echocardiogram
Acetaminophen	• **IV, intermittent:** • 15 mg/kg/dose Q 6 hours × 3-7 days	• Liver function tests • BP, murmur, respiratory status, echocardiogram

Data from Reference 49.

BP, blood pressure; IV, intravenous; PDA, patent ductus arteriosus; PNA, postnatal age; SCr, serum creatinine.

There has been interest in using acetaminophen for PDA closure. Acetaminophen has a different mechanism of action than indomethacin and ibuprofen; reducing prostaglandin concentrations by inhibiting the peroxidase component of prostaglandin synthase. While acetaminophen has minimal to no adverse medication reactions, it is less effective for PDA closure than indomethacin in preterm infants.[58,59] A number of questions still remain regarding the use of acetaminophen for PDA closure including an examination of long-term outcomes; therefore, if used in clinical practice, it is generally reserved for patients who have failed indomethacin or ibuprofen or who have contraindications to these agents (eg, thrombocytopenia, impaired kidney function, and bleeding).[58,59]

Cyanotic Heart Defects

⑥ The underlying physiology of cyanotic heart defects prevents blood from entering the pulmonary circulation to be oxygenated (eg, Tetralogy of Fallot; Figure e22-2), prevents oxygenated blood from entering the systemic circulation (eg, hypoplastic left heart syndrome; Figure e22-3), or both (eg, transposition of the great arteries; Figure e22-4). These defects can be diagnosed by prenatal ultrasound or, after a neonate remains cyanotic despite provision of 100% oxygen, by a postnatal echocardiogram. In these cases, the ductus arteriosus remains patent.[57] Prostaglandin E1 (ie, alprostadil) should be administered by continuous IV infusion at a dose of 0.05 to 0.1 µg/kg/min. Oxygen saturation, peripheral perfusion, and ductal patency as seen on echocardiogram are monitored for efficacy. Apnea and fever are common adverse medication reactions.[57] Ultimately, these patients require complex surgical repairs to correct the underlying defect and restore adequate blood flow to the pulmonary and systemic circulations.[57]

FIGURE e22-2

Tetralogy of Fallot is a cyanotic heart defect that consists of four anatomic abnormalities: ventricular septal defect (VSD), overriding aorta, pulmonary stenosis, and right ventricular hypertrophy. Pulmonary stenosis limits the amount of blood delivered to the lungs to be oxygenated; therefore, the patency of the ductus arteriosus is maintained by administration of prostaglandin E1 after birth. The patent ductus arteriosus allows some blood flow from the higher pressure systemic circulation (ie, aorta) to the lower pressure pulmonary circulation (ie, pulmonary artery) so that blood is delivered to the lungs to be oxygenated. Oxygenated blood returns from the lungs via the pulmonary veins to the left atrium and mixes in the left ventricle with deoxygenated blood that crossed the VSD before it is pumped to the systemic circulation. This defect requires surgical repair.

FIGURE e22-3

Hypoplastic left heart syndrome is a cyanotic heart defect that consists of a left ventricle that is too small to support systemic circulation. Patency of the ductus arteriosus is maintained by administration of prostaglandin E1 after birth. The patent ductus arteriosus allows some blood flow from the pulmonary circulation (ie, pulmonary artery) to shunt into the aorta providing mixed oxygenated blood to the systemic circulation. This defect requires a complex, stepwise surgical repair.

FIGURE e22-4

Transposition of the great arteries is a cyanotic heart defect that consists of malposition of the pulmonary artery and aorta resulting in parallel circuits of blood flow. Patency of the ductus arteriosus is maintained by administration of prostaglandin E1 after birth. Mixing of oxygenated and deoxygenated blood across the patent ductus arteriosus allows for some oxygen delivery to the systemic circulation. Emergent catheterization with balloon atrial septostomy to open the atrial septum and allow mixing of oxygenated and deoxygenated blood between the left and right atria is typically performed shortly after birth. Eventually, neonates with this defect require definitive surgical repair.

NEONATAL HYPOTENSION

Neonatal hypotension remains one of the most commonly encountered problems in NICU, especially in preterm infants. The prevalence is up to 50% in VLBW infants.[60] Neonatal hypotension is also associated with high morbidity and mortality. The biggest challenge with its management is that the normal physiological BP of neonates is unknown and differs by gestational and PNA. Therefore, definitions of hypotension in neonates used in clinical practice are variable. One definition of neonatal hypotension is any BP value that falls below the 5th or 10th percentile of population-based normative BP values. Using this definition, hypotension occurs in about 50% of infants.[61] Another definition of hypotension in VLBW infants is any systolic BP at which there is loss of autoregulation of organ blood flow that can cause tissue ischemia and organ damage.[62] The rationale for using this definition is that it allows clinicians to measure clinical indicators of hypotension rather than relying on numerical BP values. Most clinicians and researchers define neonatal hypotension as a mean arterial pressure (MAP) below the numerical value of the GA of the infant, as it is the easiest to use.[60] However, since BP increases with increasing PNA, this definition needs to be used with caution beyond the first several days of life. Since there is no clear consensus on the definition of neonatal hypotension, diagnosis and treatment are guided by clinical judgement and careful review of the physiological parameters of the infant.

Pathophysiology

The etiology of hemodynamic instability during the neonatal period is multifactorial. Assessment of clinical risk factors as well as physical examination can help identify the cause. BP is the product of cardiac output (CO) and SVR. Adequate organ perfusion is dependent on CO and SVR. CO is determined by HR and stroke volume (SV). Neonates often lack the ability to increase SV (in the face of low CO); therefore, they rely primarily on increased HR to compensate.

There are several causes of neonatal hypotension. Hypotension and low systemic blood flow can occur during the first days of life, due to delayed circulatory transition from intrauterine to extrauterine life; this effect is more prominent in preterm infants. In addition, the immature myocardium of preterm infants may impact their ability to adapt to the stress during circulatory transition, resulting in a decreased systemic BP in the first few days of life. By 48 hours of life, hypotension generally resolves due to increasing SVR and improved cardiac contractility.[63] Other causes of hypotension include PDA, chorioamnionitis, perinatal depression/asphyxia, immature hypothalamic-pituitary-adrenal (HPA) axis system/adrenal insufficiency, sepsis/septic shock, NEC, hypovolemia, and medications. A hemodynamically significant PDA in a VLBW infant can also cause systemic hypotension as well as decreased perfusion to the organs. Infants born to mothers with chorioamnionitis can have peripheral vasodilation and increased capillary permeability secondary to the release of cytokines, such as tumor necrosis factor and interleukin-1, as a response to inflammation.[64] Both peripheral vasodilation and increased capillary permeability can cause hypotension. Infants born with perinatal depression may also have hypotension due to myocardial dysfunction. Preterm infants have an immature HPA axis system, and although they can produce enough cortisol for growth and development, they are not able to produce adequate amounts in response to stress or illness.[65] Sepsis/septic shock and NEC, similar to chorioamnionitis, can also cause hypotension in both term and preterm infants. Although hypovolemia is not a common cause of hypotension in neonates, one should suspect this if the infant is pale with tachycardia and exhibits high blood loss.[63] Medications causing hypotension in neonates include opioids, benzodiazepines, dexmedetomidine, and exposure to maternal anesthesia.

Clinical Assessment

⑦ Appropriate treatment of neonatal hypotension is important since hypotension has been associated with impaired cerebral perfusion and ischemic damage. Because there is no clear consensus on the definition of neonatal hypotension, overall assessment of the infant's cardiovascular status should be used in addition to BP measurements. The gold standard for measuring BP is an intraarterial measurement using an umbilical arterial catheter or a peripheral arterial line. However, many clinicians have used noninvasive BP measurements as it is more readily available. Another controversy of BP measurement in neonates is whether the systolic or MAP measurement should be used. It remains unknown as to which BP measurement accurately correlates to long-term neurologic outcomes in these infants. Most clinicians will often set BP goals in an attempt to maintain adequate cerebral blood flow (CBF) and prevent ischemia (Table e22-5). Identifying maternal and neonatal factors associated with hypotension such as GA, the presence of chorioamnionitis or perinatal depression, or signs of blood loss is pertinent. Physical assessment indicative of hypotension may include tachycardia and prolonged capillary refill time. Capillary refill times of greater than 3 seconds may occur due to low CO. Tachycardia, with HR ≥ 160 bpm, is a compensatory mechanism for decreased CO. Other signs of inadequate perfusion include weak pulse, mottled skin, lethargy, metabolic acidosis, and decreased urine output. Metabolic acidosis and decreased urine output can occur as a result of inadequate organ blood flow and perfusion. Decreased urine output in preterm infants may be helpful in assessing organ perfusion. However, because of the inability to concentrate urine effectively, infants may produce adequate urine output which could be mistaken for adequate kidney function and organ perfusion. Short- and long-term complications of neonatal hypotension include IVH, periventricular leukomalacia (PVL), neurodevelopmental disability, organ failure, and death.[62,66]

TABLE e22-5

Blood Pressure Thresholds at Third Percentile According to Gestational Age

Gestational Age (weeks)	Systolic (mm Hg)	Diastolic (mm Hg)	Mean (mm Hg)
24	32	15	26
25	34	16	26
26	36	17	27
27	38	17	27
28	40	18	28
29	41	19	28
30	43	20	29
31	45	20	30

35	49	24	32
36	50	25	32

Data from Reference 67.

Treatment

8 Management of neonatal hypotension should be focused on assessment as well as treatment of the suspected etiology rather than just numerical BP values. Preterm infants are usually treated for hypotension in the first 24 hours of life.[60] The goal is to preserve organ perfusion, especially CBF. Volume expansion is the first-line therapy of hypotension, regardless of the etiology. The administration of crystalloids (eg, 0.9% normal saline) can improve preload and decrease SVR.[60] Crystalloids are usually given at a dose of 10 to 20 mL/kg intravenously. No more than one fluid bolus should be administered unless there is evidence of fluid loss or hypovolemia, since excess fluid administration has been associated with increased morbidity (eg, PDA, NEC, chronic lung disease, abnormal neurodevelopmental outcomes) and mortality. Packed red blood cell transfusions can be administered to those with hemorrhage or anemia.

Pharmacologic Therapy

The decision to select one therapeutic agent over another for neonatal hypotension should be based on the patient-specific clinical assessment of the etiology of hypotension. Medications used to treat neonatal hypotension primarily act on three receptors: α- and β-adrenergic receptors and dopaminergic receptors. Medications that affect these receptors include dopamine, dobutamine, epinephrine, and norepinephrine. Because these medications are considered vesicants, they should be administered via a central venous catheter to minimize the possibility of extravasation;

administration into an umbilical arterial catheter is not recommended. Other medications used to treat neonatal hypotension include hydrocortisone and vasopressin (Table e22-6).

TABLE e22-6

Pharmacologic Agents for Neonatal Hypotension

Medication	Site of Action	Physiological Effects	Dosing Range (μg/kg/min)	Standard Concentrations
Dopamine	Dopaminergic	Renal and mesenteric vasodilation	1-4	- 1,600 μg/mL - 3,200 μg/mL - 6,000 μg/mL
	β adrenergic	Inotrope	5-10	
	α adrenergic	Vasopressor, increased SVR and PVR	11 - 20	
Dobutamine	β_1 and β_2 adrenergic	Inotrope, decreased SVR, increased CO	5-20	- 1,000 μg/mL - 2,000 μg/mL - 4,000 μg/mL - 5,000 μg/mL
Epinephrine	$\beta_1 > \beta_2$ adrenergic	Inotrope, decreased SVR	0.05-0.1	- 16 μg/mL - 32 μg/mL - 64 μg/mL
	α_1 adrenergic	Vasopressor, increased SVR	0.1-2.5	
Norepinephrine	α_1 and α_2 adrenergic	Vasopressor, increased SVR	0.05-2	- 4 μg/mL - 16 μg/mL
Hydrocortisone	Increased sensitivity to catecholamines	Stimulates endogenous cortisol	1-3 mg/kg/day in 3 divided doses IV × 2-5 days	- 1 mg/mL - 5 mg/mL
Vasopressin	$V_1 > V_2$ receptors	Increased SVR,no inotropic effect	0.0002-0.02 unit/kg/min	- 0.04 unit/mL - 0.1 unit/mL - 1 unit/mL

Data from References 49,68.

SVR, systemic vascular resistance; PVR, pulmonary vascular resistance; CO, cardiac output; IV, intravenous.

Dopamine

Dopamine is the most commonly used medication for the treatment of neonatal hypotension and is considered first-line vasoactive agent, especially in preterm infants. However, more than 30% of preterm infants with systemic hypotension fail to respond to dopamine. Preterm infants (< 28 weeks' gestation) who receive normal saline alone require more adjunctive inotropic support compared to those who receive normal saline and dopamine. However, there are no differences in rates of mortality, IVH, PVL, and NEC.[60] Furthermore, when comparing dopamine to dobutamine, colloids, and hydrocortisone, dopamine is considerably more effective in increasing BP in preterm infants whereas dobutamine is more effective in increasing left ventricular output and CO.[69] Dopamine also increases CBF, with its effects more pronounced in hypotensive than in normotensive preterm infants. There is no difference in the incidence of tachycardia, IVH, PVL, or mortality between dopamine and dobutamine.[69] Furthermore, there are no differences in adverse neurologic outcomes between dopamine, dobutamine, epinephrine, colloids, or hydrocortisone.[69] In contrast, dopamine or dobutamine use during the first 72 hours of life in preterm infants ≤ 29 weeks' gestation increases risk of the composite of death and/or severe brain injury, severe IVH, and PVL.[70] The initial dopamine dose for treating neonatal hypotension is 5 to 7.5 μg/kg/min (range, 2-20 μg/kg/min), titrated gradually by 2.5 to 5 μg/kg/min increments until optimal BP is obtained.

Dobutamine

Dobutamine's effects on BP are not as prominent as those seen with dopamine; therefore, it is generally used as third- or fourth-line agent for hypotension.[69] However, many institutions use dobutamine as a second-line agent after maximum dose of dopamine has been reached. Furthermore, because of its pure β effects, dobutamine is the inotrope of choice for infants with myocardial dysfunction since it increases SV by increasing contractility. Tolerance due to down-regulation of β receptors can be seen after 48 to 72 hours of infusion. Effective dobutamine doses range from 5 to 20 μg/kg/min. If tachycardia occurs, reducing the dose will usually alleviate the adverse medication reactions.

Epinephrine

Epinephrine is a strong positive inotrope and increases myocardial blood flow at lower doses (0.03-0.1 μg/kg/min). Similar to dopamine, higher doses (> 0.1 μg/kg/min) of epinephrine have α receptor effects and can cause peripheral vasoconstriction. In children with septic shock, epinephrine or norepinephrine is the vasopressor agent of choice for the treatment of hypotension.[71] However, in neonates, epinephrine is typically used as a second- or third-line agent in the treatment of hypotension due to its risk of tachycardia and arrhythmias. As doses escalate (>0.5 μg/kg/min), vasoconstriction can become more intense and can result in severe tachycardia, decreased blood perfusion to the kidneys and gastrointestinal (GI) tract, and increased oxygen consumption. When comparing dopamine (2.5-10 μg/kg/min) to epinephrine (0.125-0.5 μg/kg/min) in preterm infants with hypotension, there is no difference in BP measurements. However, there are greater increases in HR, lactate concentrations, and glucose concentrations requiring insulin therapy in patients treated with epinephrine.[60,69] Additionally, CBF increases dramatically in the lower GA (< 28 weeks) with epinephrine compared to increases with dopamine among higher GA (28-32 weeks). Epinephrine infusions are typically initiated at 0.05 to 0.1 μg/kg/min; usual effective doses range from 0.5 to 4 μg/kg/min. Generally, 0.1 μg/kg/min of epinephrine is equivalent to about 10 μg/kg/min of dopamine.[68]

Norepinephrine

Norepinephrine, similar to epinephrine, stimulates both α- and β- receptors, thereby increasing both SVR and CO. However, it has less β_2 activity and can cause more potent peripheral vasoconstriction as well as positive inotropic effects. Similar to epinephrine, norepinephrine may be used as first-line vasopressor agent for the treatment of hypotension in children with septic shock.[71] However, its use for treating hypotension in neonates is limited. Norepinephrine increases BP and urine output and decreases plasma lactate concentrations when used in term and preterm infants with septic shock refractory to IV fluid boluses, high doses of dopamine and dobutamine, and hydrocortisone.[68] Infants with persistent pulmonary hypertension of the newborn (PPHN) often have increased PVR, low systemic pressure, low CO, and myocardial dysfunction. Norepinephrine also causes reductions in the pulmonary to systemic pressure ratio and an increase in systemic BP, left ventricular output, and urine output without changes in HR when used in infants with PPHN.[68] Tachycardia is the most frequent adverse medication reaction, occurring in 31% of infants. The mortality rate is high, up to 46%, and higher in infants with a younger GA. Norepinephrine may be considered as rescue therapy for infants with septic shock refractory to other inotropes. Furthermore, norepinephrine may have a role in infants with PPHN and circulatory failure because it increases both systemic and pulmonary artery pressure, thereby improving lung function. In addition, norepinephrine may be added when epinephrine doses exceed 0.1 to 0.2 μg/kg/min, as it allows for de-escalation of epinephrine and hence, less hyperglycemia and tachycardia.

Hydrocortisone

Preterm infants commonly have relative adrenal insufficiency, which can result in hypotension refractory to vasopressor medications. Hydrocortisone has become widely used and is effective in the treatment of refractory hypotension in neonates. However, due to the lack of safety data as well as the potential risk of cerebral palsy, hydrocortisone is generally not recommended for routine use for hypotension.[72] Other controversial issues regarding the use of hydrocortisone include optimal dosing regimens and duration of therapy. Doses ranging from 20 to 100 mg/m^2/day (in 3-4 divided doses) have been suggested, which is 2 to 6 times the physiologic dose. Others have used a dose of 1 mg/kg/dose every 8 hours, which is the dose to simulate endogenous physiologic secretion of cortisol.[73] Low-dose steroids (1-3 mg/kg/day) are as effective in increasing BP as high doses (> 3 mg/kg/day), while high and prolonged duration of glucocorticoid exposure can result in adverse medication reactions, including neurodevelopmental impairment and oliguria.[73,74] Infants with volume-resistant hypotension, undergoing therapeutic hypothermia who receive low-dose hydrocortisone (0.5 mg/kg/dose every 6 hr) plus dopamine more often achieve targeted MAP compared to those who receive dopamine alone.[75] Additionally, the duration of cardiovascular support and cumulative and peak inotrope dosage are much lower in patients receiving hydrocortisone. Serum cortisol levels are low in patients receiving hydrocortisone plus dopamine or dopamine alone.[75] Some clinicians measure cortisol concentrations prior to hydrocortisone administration to determine adrenal insufficiency. Although cortisol concentrations do not correlate with GA, BW, or response to hydrocortisone therapy, infants who are not cortisol deficient have less improvement in BP measurements, more hyperglycemia, and increased death, independent of the hydrocortisone dose.[74] Therefore, hydrocortisone therapy should be avoided in infants who are not cortisol deficient due to these increased risks, independent of hydrocortisone dose, GA, or BW.

Upon initiation of hydrocortisone in infants with vasopressor-resistant hypotension, clinicians need to find a balance between optimal dosing and duration and potential adverse medication reactions. One recommendation is to give a single dose of hydrocortisone and determine if there is a response. If there is no response within 2 to 4 hours, further dosing is not recommended. However, if BP improves, subsequent doses of 0.5 mg/kg/dose every 12 hours for <34 weeks GA and every 8 hours for >34 weeks GA are recommended.[73] Based on cardiovascular status of the infant, the dose and timing of subsequent administrations can be modified. Other common dosing regimens include hydrocortisone 1 mg/kg/dose every 8 hours. Hydrocortisone can be slowly discontinued once an infant is either weaned off vasopressors completely or when vasopressors doses have been decreased. Infants should be monitored for signs of adrenal insufficiency, such as hypotension, hyponatremia, or decreased urine output. Hydrocortisone therapy should be restarted at the lowest dose if symptoms reoccur.

Vasopressin

In patients with septic shock, the body is not able to produce large amounts of endogenous vasopressin, which can lead to hypotension commonly seen in those with uncompensated septic shock. Vasopressin is effective in increasing BP and urine output and decreases the need for catecholamines without ischemic adverse effects.[76] Vasopressin is equally as effective as dopamine in increasing BP in ELBW infants with hypotension during the first 24 hours of life.[69,76] Infants treated with vasopressin require fewer surfactant doses, have lower $PaCO_2$ values, and exhibit less tachycardia compared to infants treated with dopamine. Furthermore, there are no differences in serum sodium or lactate concentrations or the number of infants with hyponatremia, before and during vasopressin administration. Additionally, low dose vasopressin (0.0003 units/kg/min) is associated with improvements in BP and reduction in oxygenation index, lactic acidosis, and inotropic support in infants with PPHN and catecholamine refractory shock.[77] Vasopressin administration is not associated with infants developing NEC.[76,77] While vasopressin may be considered as rescue therapy when high-dose catecholamines and steroids fail to increase BP in infants with refractory hypotension, its role as first-line treatment of neonatal hypotension is unclear at this time. Potential adverse medication reactions of vasopressin are hyponatremia and poor end organ perfusion; however, it is difficult to assess if the poor end organ perfusion is due to vasopressin or a clinical manifestation of septic shock or refractory hypotension. The initial vasopressin dose is 0.0002 to 0.0003 units/kg/min; doses as high as 0.02 units/kg/min have been used.[77] A common error with vasopressin is the dosing units as vasopressin can be prescribed as "units/kg/*min*" vs "units/kg/*hr*" vs "*milliunits*/kg/min" depending on the indication for use. Caution should be used when prescribing and preparing vasopressin for neonates.

Administration Challenges

One of the challenges with dosing and administering inotropes in preterm infants is the low infusion rates needed for continuous IV medications. Oftentimes, the flow rates of these medications can be as low as 0.1 to 0.2 mL/hr. These low infusion rates, as well as the dead space volumes of the IV catheter and connection, can lead to longer times to reach onset and steady state. This can result in variable and unpredictable doses delivered to the infant especially after a change in dosing. Factors that may influence flow rate variability when medications are infused at low rates include volume of the IV administration set, presence of valves or inline filters, and hydrostatic pressure changes.[78] Therefore, it is important to recognize these factors when prescribing medications with narrow therapeutic indices especially when infusion rates are low and to monitor for clinical efficacy and potential adverse medication reactions. In 2008, the American Society of Health-System Pharmacists (ASHP) recommended the development and implementation of national standardized concentration of IV medications, known as the *Standardize 4 Safety*, to reduce medication errors (administration and preparation) and improve transition of care.[79] Patients at greatest risk for these errors are often the most vulnerable populations, including neonates. When implementing standard concentrations of IV medications, it is important to select concentrations that allow for appropriate infusion rates.

MANAGEMENT OF PAIN AND SEDATION

Historically, it was believed that neonates especially those born prematurely were unable to perceive pain. Although it is now widely known that this belief was incorrect, NICU patients routinely undergo multiple painful procedures without analgesic therapy being provided.[80–82] Failure to provide sufficient analgesia may occur for various reasons including inadequate pain assessment and fear of adverse medication reactions. The consequences of untreated pain can be significant including altered and exaggerated responses to painful and nonpainful stimuli, physiological instability, abnormal brain development, and altered neurodevelopment.[82]

In the NICU, two types of pain typically are encountered: (1) acute pain which is associated with surgeries or procedures (eg, heel-stick for blood collection, endotracheal intubation) and (2) prolonged pain which is caused by disease (eg, NEC) or some interventions (eg, mechanical ventilation, chest tubes).[83,84] Environmental factors (eg, temperature, soiled diaper, positioning) may also contribute to discomfort. These should be addressed and noxious stimuli should be removed before a pharmacological intervention is employed to manage pain or agitation.[83]

Assessment of Pain and Agitation

⑨ Self-reporting is the standard method used to assess comfort in most patient populations, but is not plausible in the preverbal neonatal population.[80,81] Therefore, clinicians caring for neonates must rely on physiological (eg, HR change) and behavioral (eg, facial grimace, crying) parameters to evaluate the degree of pain and sedation.[82,83] These observations can be subjective and biased by perceptions and beliefs of healthcare providers. Additionally, the presence of a pain response and its magnitude may be affected by GA, PNA, illness severity, and neurological impairment which further complicates assessment.[82,84] The use of pain assessment scales is recommended to better standardize this practice.[82,83] Many tools have been developed in an attempt to better assess pain in neonates; however, most have not been validated using psychometric testing.[82,83] Furthermore, most of these tools have only been validated for procedural (ie acute) pain not prolonged pain.[84] Some tools utilize both physiological and behavioral parameters while others only consider behavioral variables.[80,82] The tools have also been validated in varying gestational and PNA ranges.[82] These factors make it unlikely that one pain assessment tool will be appropriate for use in all NICU patients.[80] Some of the most commonly used tools, which are generally known by acronyms, are described in Table e22-7. Regardless of the tool used, assessment should be repeated after each intervention to determine its effectiveness in relieving pain.

TABLE e22-7

Commonly Used Neonatal Pain Assessment Tools

Tool Name	Type(s) of Pain Assessed	Population	Parameters Included
PIPP (Premature Infant Pain Profile)	Acute	28-40 week GA	GA Behavioral state HR increase O_2 saturation decrease Brow bulge Eye squeeze Nasolabial furrow
NIPS (Neonatal Infant Pain Score)	Acute	26-41 week GA (PNA: up to 6	Facial expression

		weeks)	• Crying • Breathing pattern • Limb movements • State of arousal
NFCS (Neonatal Facial Coding System)	• Acute • Prolonged	24-32 week GA (PNA: up to 56 days)	• Brow lowering • Eye squeeze • Nasolabial furrow • Lip opening/pursing • Mouth stretch • Taut tongue • Chin quiver
N-PASS (Neonatal Pain, Agitation, and Sedation Scale)	• Acute • Prolonged • Level of sedation	23-40 week GA (PNA: up to 100 days)	• Behavioral state • Facial expression • Crying • Tone of extremities • HR, BP, respiratory rate, O_2 saturation
CRIES (Cry, Requires oxygen, Increased vital signs, Expression, Sleeplessness)	Prolonged	27-40 week GA (PNA: up to ~8 months)	• Crying • Requires O_2 to keep saturation >95% (0.95) • Increased HR, blood pressure • Facial expression • Sleep / alertness
COMFORT scale	Prolonged	24-42 week GA	• Calmness / alertness • Movement • Facial tension • Respiratory rate • Crying • Tone

Data from References 80,82.

BP, blood pressure; GA, gestational age; HR, heart rate; PNA, postnatal age.

Assessment of nonpain-related distress can be even more difficult in neonates. Many of the physiological and behavioral findings overlap with those observed in neonates suffering from pain, drug withdrawal, or delirium.[83] Agitation or undersedation may contribute to accidental displacement of endotracheal tubes and IV catheters, as well as anxiety and fear in neonates because they are developmentally unable to understand and cope with stressful situations.[83] Conversely, oversedation can result in a prolonged need for mechanical ventilation, longer duration of hospitalization, and increased healthcare costs.[83] The N-PASS (Table e22-7) is one of the few tools available to assess the level of sedation in neonates.[82]

Nonpharmacologic Treatment Options

The first steps toward minimizing pain and agitation in neonates should be to reduce the number of painful interventions (eg, limit blood collection) and to coordinate or "bundle" bedside care (eg, diaper changes, physical examinations, endotracheal tube suctioning) to allow the neonate longer periods of restfulness.[81] When painful procedures are necessary, nonpharmacologic modalities should be the first tier of interventions used. Nonpharmacologic therapies often used in the NICU include swaddling, non-nutritive sucking, skin-to-skin care (commonly called "kangaroo care"), massage, and breast or bottle feeding.[81,82] These interventions are most effective when used in combination with each other or as adjuvants to pharmacologic therapies.[81,85]

Pharmacologic Treatment Options

Medication selection is dependent on the indication (ie, type and severity of pain, need for sedation) and the adverse medication reactions profile. Neonatal dosing recommendations for many analgesics and sedatives are frequently not supported by well-designed pharmacokinetic and outcomes studies in neonates of various gestational and postnatal ages (Table e22-8).

TABLE e22-8

Neonatal Dosing Recommendations for Commonly Used Analgesics and Sedatives

Medication	Uses	Dosing Regimen	Comments
Sucrose 24% solution	Analgesia; mild procedural pain	• < 1 kg: 0.1 mL/dose • 1-2 kg: 0.1-0.2 mL/dose • > 2 kg: 0.1-0.5 mL/dose	• Administer 1-2 minutes prior to procedure • May be applied to pacifier or directly to tongue • Do not exceed 3 doses per procedure
Acetaminophen	• Analgesia; mild-to-moderate postoperative or prolonged pain • Analgesia; moderate-to-severe postoperative pain when used in combination with an opioid	• **Oral:** • GA 28-32 weeks: 10-12 mg/kg/dose Q 6-8 hours; max dose 40 mg/kg/day • GA 33-37 weeks: 10-15 mg/kg/dose Q 6 hours; max dose 60 mg/kg/day • Term, ≥ 10 days: 10-15 mg/kg/dose Q 4-6 hours; max dose 75 mg/kg/day • **IV:** • PMA 28-32 weeks: 10 mg/kg/dose Q 12 hours; max dose 22.5 mg/kg/day • PMA 33-36 weeks: 10 mg/kg/dose Q 8 hours; max dose 40 mg/kg/day • PMA ≥ 37 weeks: 10 mg/kg/dose Q 6 hours; max dose 40 mg/kg/day	Not effective for acute procedural pain
Morphine	Analgesia; moderate-to-severe prolonged or postoperative pain	• **IV, intermittent:** • 0.05-0.1 mg/kg/dose Q 4-6 hours	• Preterm neonates may be more susceptible to hypotension, respiratory depression, apnea

		• **IV, continuous:** • 0.01-0.03 mg/kg/hr	• Titrate to effect • Practitioners should be aware of potential adverse effects on neurodevelopment
Fentanyl	Analgesia; moderate-to-severe acute procedural pain, prolonged, or postoperative pain	• **IV, intermittent:** • 0.5-3 μg/kg/dose Q 2-4 hours • **IV, continuous:** • 0.5-3 μg/kg/hr	• Administer bolus over 3-5 minutes, more rapid rates may cause chest wall rigidity • Titrate to effect
Midazolam	Sedation; procedural or prolonged	• **IV, intermittent:** • 0.05-0.1 mg/kg/dose • **IV, continuous:** • GA 24-26 weeks: 0.02-0.03 mg/kg/hr • GA 27-29 weeks: 0.03-0.04 mg/kg/hr • GA ≥30 weeks: 0.03-0.06 mg/kg/hr	• Myoclonus may occur especially in preterm neonates • Titrate to effect • Practitioners should be aware of potential adverse effects on neurodevelopment
Dexmedetomidine	Sedation, analgesia; prolonged	• **IV, continuous:** • 0.1-0.3 μg/kg/hr	Limited neonatal data

GA, gestational age; IV, intravenous; PMA, postmenstrual age.

Sucrose

Oral sucrose administered 2 minutes prior to a mildly to moderately painful procedure reduces Premature Infant Pain Profile (PIPP) scores.[86] The exact mechanism of action is unknown, but it has been postulated that sucrose stimulates endogenous opiate and endorphin pathways to mediate the pain response. The optimal dose is unknown, but the typical dose used in practice is 0.1 to 1 mL of 24% sucrose administered on the tongue or buccal surface. Its effects are potentiated when combined with non-nutritive sucking (eg, pacifier) and/or swaddling. Since the duration of effect is about 4 minutes, doses may need to be repeated during longer procedures.[82] While sucrose administration is safe for treating a single painful procedure, there are concerns that repeated doses may be associated with hyperglycemia, NEC, and worse neurodevelopment.[82,86]

Acetaminophen and Cyclooxygenase-1 Inhibitors

Acetaminophen is used for mild-to-moderate pain in the NICU although its slow onset of effect compared to other options does not make it an ideal agent for preventing and treating acute procedural pain (eg, heelstick, venipuncture, intubation).[85] When used in combination with opioids for treating neonates with moderate-to-severe postoperative pain, acetaminophen reduces opioid requirements by more than 50%.[82,87]

Acetaminophen is primarily metabolized by glucuronidation and oxidation in older children and adults; however, the activity of these pathways is low in neonates especially those born prematurely. Instead, sulfation is the primary pathway through which acetaminophen is metabolized in neonates. This may provide a protective effect to the neonate against acetaminophen-induced acute liver injury because *N*-acetyl-*p*-benzoquinone imine (NAPQI), the toxic metabolite, is formed by oxidation.[88] Additionally, NAPQI is detoxified by glutathione, the synthesis of which is increased in neonates.[89] There may be an association between prenatal and early postnatal exposure to acetaminophen and the development of atopy, autism spectrum disorder, and attention deficit hyperactivity disorder. While causation and a pathologic mechanism have not been proven, this potential link warrants consideration and further evaluation.[87]

Cyclooxygenase-1 inhibitors (eg, ibuprofen) may not be as effective in premature neonates because of decreased receptor expression in the spinal cord.[82] This finding along with associated adverse medication reactions (eg, nephrotoxicity, platelet dysfunction, GI bleeding) make cyclooxygenase-1 inhibitors a non-ideal choice for analgesia in neonates.

Opioids

⑩ Opioids are generally used for moderately to severely painful procedures in the NICU. Morphine and fentanyl are the most commonly used agents from this class.[82,85] Although the American Academy of Pediatrics recommends that analgesia should be provided during painful procedures (eg, circumcision, chest tube placement, endotracheal intubation), the safety and efficacy of scheduled/continuous analgesia during prolonged painful events (eg, mechanical ventilation) remain in question.[81,82] Despite a lack of evidence to support the practice, opioids are often administered to mechanically ventilated neonates to prevent pain and provide sedation.

Morphine undergoes glucuronidation to two active metabolites. Neonates younger than 10 postnatal days have about half the glucuronidation activity as those who are older. Maturation of glucuronidation continues over the first few months. This suggests that younger neonates, especially those under 10 days, will require lower doses of morphine than their older counterparts.[87,88] Similarly, fentanyl clearance is correlated with GA. Neonates with younger GA have slower fentanyl clearance suggesting that lower doses should be used in this population. Increases in clearance occur around 2 weeks of PNA.[90]

Hypotension associated with morphine use, especially after a bolus dose, may occur for preterm neonates, while this adverse medication reaction is less common with fentanyl. This difference is attributed to histamine release that occurs in response to morphine administration.[81,85] Both agents impair GI motility, but fentanyl causes less dysmotility.[81] Respiratory depression may occur with both agents, potentially prolonging mechanical ventilation.[81] Rapid administration (ie, dose infused over less than 3 to 5 minutes) of fentanyl is associated with chest wall rigidity.[82,85] In such patients, naloxone or a neuromuscular blocking agent may be required to relax the respiratory muscles and facilitate ventilation.[85] Tachyphylaxis may occur with both agents, but develops more rapidly during treatment with fentanyl.[81] Prolonged exposure to opioids can lead to physiological dependence and predispose a neonate to withdrawal if these agents are abruptly discontinued or too rapidly tapered off.[82,83]

The effect of opioids on short- and long-term neurological outcomes is unclear. Opioid exposure during early brain development may result in neural cell apoptosis and reduced neuronal concentration, manifesting as reduced brain growth, impaired motor movement, and learning disability.[81] Preterm neonates who receive continuous infusion morphine or midazolam while mechanically ventilated may have a higher incidence of IVH, PVL, or death compared to neonates who receive fentanyl or no sedative or analgesic agent.[91–94] Long-term complications such as impaired motor development, lowered intelligence quotient, and altered short-term memory may occur in preterm neonates exposed to morphine.[81,82]

Benzodiazepines

Benzodiazepines are commonly used for sedation in the NICU. Unlike opioids, they do not provide a beneficial analgesic effect.[82] Despite limited data regarding efficacy and dosing, midazolam is the most commonly used benzodiazepine in neonates.[82,95] It is preferred because of its shorter time for elimination compared to lorazepam or diazepam and availability as a preservative-free product.[85,95]

When used in combination with opioids, benzodiazepines can potentiate the respiratory depression and hypotension associated with opioid use.[82] Neonates receiving benzodiazepines may exhibit myoclonic jerks which may be misconstrued as seizures.[81] Also, neonates who receive midazolam for sedation during mechanical ventilation may have longer lengths of hospital stay than those who do not receive midazolam.[95] Early benzodiazepine exposure may result in reduced formation and increased apoptosis of neural cells which could result in poor long-term neurodevelopment.[81]

Dexmedetomidine

Dexmedetomidine, an α2-adrenergic receptor agonist, is an effective sedative and analgesic agent for adult patients and may be efficacious in neonates.[96–100] The optimal dosing range has not been delineated, but younger neonates require lower weight-based doses.[101] Dexmedetomidine offers the advantage of not affecting respiratory drive; therefore, neonates treated with it require shorter durations of mechanical ventilation than those sedated with morphine or benzodiazepines.[98] Gastric motility is minimally altered by dexmedetomidine thus neonates tolerate enteral feeding sooner than when treated with opioids.[98] Additionally, dexmedetomidine may have neuroprotective effects.[85,98] However, the propensity for dexmedetomidine to cause hypotension is a concern for its use in neonates.[85,100] As with opioid and benzodiazepine use, withdrawal symptoms may occur upon weaning and discontinuation of dexmedetomidine.[100]

CONCLUSION

The neonatal population is complex owing to differences in anatomy and physiology when compared to older children and adults. These differences impact disease presentation; medication selection, dosing, and monitoring; as well as the patient's response to medication therapy. Clinicians need to be aware of the complexity of this population to assist with optimizing medication therapy, ensuring patient safety, and identifying research opportunities.

ABBREVIATIONS

AKI	acute kidney injury
BP	blood pressure
BPD	bronchopulmonary dysplasia
BW	birth weight
CPR	cardiopulmonary resuscitation
CBF	cerebral blood flow
CHD	congenital heart defect
CNS	central nervous system
CO	cardiac output
CONS	coagulase negative Staphylococcus
CRP	C-reactive protein
CSF	cerebrospinal fluid
EID	extended interval dosing
ELBW	extremely low birth weight
EOS	early-onset sepsis
GI	gastrointestional

GA	gestational age
GBS	group B Streptococcus
HPA	hypothalamic-pituitary-adrenal
HR	heart rate
HSV	herpes simplex virus
I/T	immature to total ratio
IO	intraosseous
IV	intravenous
IVH	intraventricular hemorrhage
LOS	late-onset sepsis
LP	lumbar puncture
MAP	mean arterial pressure
MIC	minimum inhibitory concentration
MRSA	Methicillin resistant *Staphylococcus aureus*
NAPQI	*N*-acetyl-*p*-benzoquinone
NEC	necrotizing enterocolitis
NICU	neonatal intensive care unit
PCT	procalcitonin
PN	parenteral nutrition
PDA	patent ductus arteriosus
PMA	postmenstrual age
PNA	postnatal age
PPHN	persistent pulmonary hypertension of the newborn
PVL	periventricular leukomalacia
PIPP	Premature Infant Pain Profile
PVR	pulmonary vascular resistance

SV	stroke volume
SVR	systemic vascular resistance
TDM	therapeutic drug monitoring
VLBW	very low-birth weight
WBC	white blood cell count

SELF-ASSESSMENT QUESTIONS

1. The pharmacist plays a key role on the interprofessional team in the NICU for all of the following reasons except:

   A. Ability to diagnose diseases specific to the neonatal population

   B. Experience with conducting clinical research

   C. Knowledge of age-related pharmacokinetic changes

   D. Understanding of technology (eg, “smart” IV pumps, dose-range checking)

2. Why is the IV route preferred over the endotracheal route for administration of epinephrine during a newborn cardiopulmonary arrest?

   A. The optimal dose of IV epinephrine for neonatal resuscitation has been well studied.

   B. IV access is readily available in neonates who are likely to experience a cardiopulmonary arrest.

   C. Efficacy of endotracheal epinephrine may be lower because of impaired absorption from reduced blood flow to the pulmonary circulation.

   D. Adverse medication reactions occur more commonly when epinephrine is administered by the endotracheal route.

3. A newborn has respiratory depression immediately after birth resulting in a respiratory acidosis. The newborn's HR is 80 bpm. The mother has a history of chronic oxycodone use. Which intervention is most appropriate for this newborn at this time?

   A. Epinephrine

   B. Naloxone

   C. Sodium bicarbonate

   D. Supportive respiratory care

4. Which of the following adverse medication reactions is most likely to be experienced by a neonate treated with indomethacin for closure of a patent ductus arteriosus?

   A. Thrombosis

   B. Neutropenia

   C. Acute kidney injury

   D. Anaphylaxis

5. What is the rationale for administering prostaglandin E1 (ie, alprostadil) to a newborn with hypoplastic left heart syndrome?

   A. Maintain patency of the ductus arteriosus to allow systemic to pulmonary shunting

   B. Maintain patency of the ductus arteriosus to allow pulmonary to systemic shunting

   C. Promote closure of the ductus arteriosus to prevent systemic to pulmonary shunting

   D. Promote closure of the ductus arteriosus to prevent pulmonary to systemic shunting

6. A preterm neonate born at 27 weeks gestational age is requiring multiple needlesticks for frequent blood collections. Which pain assessment tool would be best to evaluate this neonate's pain?

   A. COMFORT

   B. CRIES

   C. NIPS

   D. PIPP

7. A neonate born at 29 weeks gestational age requires endotracheal intubation because of sepsis-associated respiratory failure at 30 days postnatal age. Which intervention would be most appropriate to prevent pain in this neonate?

   A. Acetaminophen

   B. Fentanyl

   C. Sucrose

   D. No analgesic agent should be recommended

8. What is a potential long-term detrimental effect of prolonged morphine exposure in neonates?

   A. Decreased visual acuity

   B. Lowered intelligence quotient

   C. Respiratory depression

   D. Sedation

Please refer to the following case for questions #9-10:

SM is an ex 25 weeks' gestation preemie who is now 21 days old, postmenstrual age of 28 weeks. Overnight, SM has multiple apneas and desaturations requiring mechanical ventilation. The NICU does not have a high rate of methicillin-resistant *Staphylococcus aureus* (MRSA).

9. The medical team would like to initiate IV antibiotic therapy for presumed sepsis. Which empiric antibiotic regimen is most appropriate for SM at this time?

   A. Gentamicin and vancomycin

   B. Nafcillin and gentamicin

   C. Ampicillin and gentamicin

   D. Cefepime and vancomycin

10. SM's blood culture is positive for *E. coli*. The cerebrospinal fluid (CSF) cell counts are normal and CSF culture is negative. What is the optimal duration of antibiotic therapy for SM?

   A. 2 days

   B. 7 days

   C. 10 days

   D. 21 days

11. What are the most common pathogens associated with early-onset sepsis in neonates?

    A. *Listeria monocytogenes*, *Staphylococcus* coagulase negative, and Group B *Streptococcus*

    B. *Enterobacteriaceae*, *Staphylococcus aureus*, and Enterococcus

    C. *Escherichia coli*, Group B *Streptococcus*, and *Listeria monocytogenes*

    D. *Staphylococcus* coagulase negative, *Klebsiella pneumoniae*, and *Enterobacter cloacae*

12. The NICU medical team would like to initiate prophylactic fluconazole for all high risk preterm infants. Which statement is correct with regards to the administration of prophylactic fluconazole?

    A. All preterm infants born less than 1,500 g should receive prophylactic IV fluconazole 12 mg/kg/dose for 6 weeks.

    B. NICUs with high rates of invasive candidiasis should prescribe prophylactic fluconazole for high-risk very low birth weight infants.

    C. Prophylactic fluconazole has not been shown to significantly decrease the incidence of invasive candidiasis in very low birth weight infants.

    D. Amphotericin should be used rather than fluconazole for the prevention of invasive candidiasis in very low birth weight infants.

Please refer to the following case for questions #13-14:

JR is a 27 weeks' gestation infant, birth weight of 840 g, born to a 26-year-old woman with placenta abruptio. Apgar scores were 1, 3, and 7 at 1, 5, and 10 min, respectively. JR was immediately intubated in the delivery room and transferred to the NICU. At about 20 min of life, JR had BP instability with MAP ranging from 20 to 25 mm Hg. One dose of normal saline 0.9% NaCl 20 mL/kg was infused over 30 min with minimal improvement of MAP.

13. The neonatologist would like to initiate a pharmacologic agent for JR's hypotension. Which medication is the most appropriate first-line treatment for JR's neonatal hypotension?

    A. Dobutamine

    B. Dopamine

    C. Epinephrine

    D. Hydrocortisone

14. There is evidence of myocardial dysfunction on JR's echocardiogram. Which treatment is most appropriate for JR at this time?

    A. Dobutamine

    B. Dopamine

    C. Epinephrine

    D. Norepinephrine

15. Which parameters are measurements of cardiac instability in neonates?

    A. White blood cell count, urine output, and temperature

    B. Capillary refill time, heart rate, and C-reactive protein level

    C. Temperature, heart rate, and oxygen saturation

    D. Capillary refill time, urine output, and heart rate

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Identification and diagnosis of diseases is the primary role of physicians on the medical team. Pharmacists are trained, and skilled, in applying pharmacokinetics to medication dosing, utilizing technology to promote medication safety, and conducting research to improve the efficacy and safety of medications.

2. **C.** Shunting of blood from right-to-left (ie, from the pulmonary artery to the aorta) through the patent ductus arteriosus reduces blood flow to the lungs and; therefore, absorption of endotracheally administered epinephrine into the systemic circulation is reduced. Thus, decreased efficacy of endotracheal epinephrine makes IV the preferred route of administration despite potential difficulties with obtaining IV access and the lack of studies evaluating the optimal dose.

3. **D.** In utero exposure to oxycodone is the likely cause of this neonate's respiratory depression; however, naloxone is not recommended to reverse the effect because its administration may precipitate withdrawal symptoms. Sodium bicarbonate may correct metabolic acidosis or mixed acidosis, but could worsen respiratory acidosis. The newborn's heart rate is adequate so epinephrine is not indicated. Supplemental oxygen and positive pressure ventilation will support the newborn's respiratory effort until the respiratory depressant effects of oxycodone wear off.

4. **C.** The most common adverse medication reactions of the cyclooxygenase inhibitors (ie, indomethacin, ibuprofen) used to close the patent ductus arteriosus are AKI, thrombocytopenia, bleeding, and spontaneous intestinal perforation.

5. **B.** The left ventricle of neonates with hypoplastic left heart syndrome is not developed enough to support systemic circulation. Therefore, the ductus arteriosus (connecting the pulmonary artery to the aorta) must remain patent to allow blood to shunt from the pulmonary circulation to the systemic circulation.

6. **C.** This newborn is experiencing acute procedural pain. The NIPS tool has been validated for this patient's gestation age and type of pain. PIPP is validated in neonates born between 28 and 40 weeks. COMFORT and CRIES are validated for prolonged pain (eg, from prolonged intubation and mechanical ventilation).

7. **B.** Premature neonates are capable of experiencing pain; therefore, this patient population should receive appropriate interventions to prevent and treat pain. Endotracheal intubation is considered a moderately painful procedure. Because this procedure needs to be performed quickly, an agent with a longer onset of action such as acetaminophen would not be appropriate. Sucrose is a more appropriate intervention for mildly painful procedures (eg, heel sticks for blood collections) and requires 1 to 2 min for onset of effect. Fentanyl has a quick onset of effect and is recommended for moderate-to-severe acute procedural pain.

8. **B.** Respiratory depression and sedation are known short-term adverse medication reactions of opioids; however, tolerance typically develops with prolonged use. Evidence of neural cell apoptosis, reduced neuronal concentration, and reduced brain growth resulting from prolonged morphine exposure are thought to be associated with learning disabilities and lower intelligence quotient. Altered visual acuity may be a complication of prematurity, but has not been associated with opioid exposure.

9. **B.** This patient has concerns for late-onset sepsis (LOS) since SM is 21 days old and common pathogens associated with LOS are usually hospital acquired. Vancomycin, in combination with gentamicin, has traditionally been the first-line empiric therapy for LOS in neonates, mainly due to the prevalence of coagulase-negative *Staphylococcus* (which are generally resistant to antistaphylococcal penicillins) and concern over methicillin-resistant *Staphylococcus aureus* (MRSA). However, due to the concerns over the use of vancomycin in this population, including potential adverse medication reactions (eg, nephrotoxicity, ototoxicity) and the development of resistant organisms, particularly enterococcal and staphylococcal isolates, vancomycin use should be limited to cases of MRSA or if blood culture isolates reveal coagulase-negative *Staphylococcus*, at which time, nafcillin can be replaced with vancomycin. Ampicillin and gentamicin are the antibiotics of choice for the treatment of early-onset sepsis. Cefepime should be reserved for patients with resistant gram-negative organisms.

10. **C**. SM has *E. coli* bacteremia and hence, the duration of antibiotic therapy for bacteremia is 10 to 14 days. SM does not have bacterial meningitis since the CSF cell counts are normal and CSF culture is negative. If SM has bacterial meningitis, the duration of antibiotic therapy is 14 to 21 days depending on the organism.

11. **C**. Early-onset sepsis in neonates is acquired either transplacentally or via ascending bacteria from the vaginal environment due to ruptured

amniotic membranes. Hence, the common organisms are Group B Streptococcus (also known as *Streptococcus agalactiae*) and *E. coli*. Other pathogens include *Listeria monocytogenes*, other streptococci (most commonly viridans group streptococci), and Enterococcus species. *Staphylococcus* coagulase negative, *Staphylococcus aureus*, and other Enterobacteriaceae are hospital-acquired pathogens commonly associated with late-onset sepsis.

12. **B.** Very-low-birth weight (VLBW) infants are at highest risk for *Candida* species colonization. Prophylactic fluconazole significantly decreases the incidence of invasive candidiasis, *Candida* species colonization, and mortality in VLBW and extremely-low-birth-weight (ELBW) infants. However, there is concern for the potential development of resistant pathogens as well as adverse medication reactions from prolonged use of fluconazole. Therefore, the IDSA guidelines only recommend prophylactic fluconazole for all ELBW born in NICUs with high rates (> 10%) of invasive candidiasis at a dose of 3 to 6 mg/kg/dose twice weekly for 6 weeks orally or parenterally. If fluconazole is not available or if there are concerns for resistance, oral nystatin at dose of 100,000 units three times a day for 6 weeks can be used as an alternative in VLBW infants. Amphotericin B deoxycholate should not be used for prophylaxis; instead, it is the medication of choice for the treatment of invasive candidemia in neonates.

13. **B.** Dopamine is the first-line vasoactive agent of choice for neonatal hypotension, especially in preterm infants mainly due to its effects on the α-adrenergic receptors. When compared to dobutamine and hydrocortisone, dopamine is significantly more effective in increasing BP. Similar to dopamine, epinephrine at higher doses (>0.1 μg/kg/min) has α-adrenergic receptor effects and can cause peripheral vasoconstriction, severe tachycardia, and arrythmias. Due to its safety profile, epinephrine is usually reserved as a second- or third-line agent for the treatment of neonatal hypotension. Since preterm infants may have relative adrenal insufficiency, oftentimes, they are refractory to vasopressor medications. Hydrocortisone is effective for the treatment of refractory hypotension in neonates. However, due to the potential risk of cerebral palsy, it is generally not recommended as routine use in neonates.

14. **A.** Dobutamine exerts its effects mainly on β-receptors and therefore is the inotrope of choice for infants with myocardial dysfunction since it increases SV by increasing contractility. Dopamine, epinephrine, and norepinephrine stimulate both α- and β-receptors.

15. **D.** Physical assessment indicative of cardiac instability or hypotension may include tachycardia, prolonged capillary refill time, decreased urine output, and metabolic acidosis. WBC, C-reactive protein, and temperature can all be used to assess sepsis which can result in hypotension. However, they are not clinical signs of cardiac instability.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter e23: Geriatrics: Physiology of Aging

Krista L. Donohoe; Elvin T. Price; Tracey L. Gendron; Patricia W. Slattum

KEY CONCEPTS

KEY CONCEPTS

① The population of people 65 years and older is increasing.

② Age-related changes in physiology affect the functions of various organ systems and contribute to the onset of diseases.

③ Age-related changes in physiology can affect the pharmacokinetics (PK) and pharmacodynamics (PD) of numerous medications.

④ Successful aging is determined by individually defined measures of well-being that include maximizing health span and socio-environmental engagement.

BEYOND THE BOOK

BEYOND THE BOOK

Pair up with a classmate and brainstorm a list of age-related changes that occur in the human physiology and the effects they may have on pharmacokinetics (PK)/pharmacodynamics (PD) of medications in older adults.

Interview an older adult and obtain a medication history. Using their medication list, determine the effects that age-related changes in PK/PD will have on the medications and ensure they are appropriately dosed for older adults.

INTRODUCTION

Medications can cure or palliate medical conditions in older adults, however, they can also cause a number of drug-related problems. Prevention of drug-related problems requires that health professionals be knowledgeable about the changes that occur with aging and the implications this has on prescribing, monitoring, and evaluating medication regimens in older adults. This chapter will focus on the epidemiology of aging, mechanisms of aging, physiologic changes due to aging with an emphasis on the age-related changes in pharmacokinetics (PK) and pharmacodynamics (PD) of medications, and successful aging to maximize health span and quality of life.

EPIDEMIOLOGY OF AGING

①The proportion of persons 65 years and older is increasing worldwide. In 2019, the worldwide number of people aged 65 years or older was 703 million, and this is projected to double to 1.5 billion by 2050.[1] In the United States, the population of older adults has changed from a pyramidal shape to a pillar.[2] The rectangular shape will be top heavy in 2050 because of the large numbers of births in the latter half of the 20th century. In 2018, 16% of the population was considered geriatric in the United States, and in 2050 it is projected to be 22% and 23.4% by 2060.[3] In 2034, the older adult population will outnumber children under 18 years old for the first time in US history.[2]

The population is aging due to people having fewer children and living longer. In the United States, the life expectancy in 2018 at birth is 76.2 years for men and 81.2 years for women.[4] At age 65 and 85 years old, respectively, men are projected to have 18.1 and 6 years of life remaining, compared to 20.7 and 7 years for women.[3] However, based on provisional data for the first half of 2020, US life expectancy has declined due to COVID-19 global pandemic.[5]

Older adults often have multiple chronic conditions and thus need to see a number of specialists and healthcare providers. In 2018, the three most frequently reported chronic health conditions in the United States for adults 65 and older were hypertension, arthritis, and heart disease.[3] Women have a higher prevalence of arthritis (54% vs 46%) and asthma (14% vs 9%), while men have higher rates of heart disease (35% vs 24%), cancer (27% vs 25%), and diabetes (25% vs 19%).[3] In 2018, the six leading causes of death among persons 65 years and older were: heart disease, cancer, chronic lower respiratory diseases, stroke, Alzheimer's disease, unintentional injuries, and influenza and pneumonia. Heart disease and cancer were the top two leading causes of death.[3] COVID-19 has had a significant impact on life expectancy and mortality during the global pandemic.[5]

Older adults have a high prevalence of chronic diseases, and this means they are using numerous medications on a long-term basis. This "polypharmacy" can lead to potential drug-related problems, such as drug-drug interactions.[6–8] To provide the best pharmacotherapy for this diverse and heterogeneous population of older adults, their health care providers need to understand the mechanisms of physiologic changes that occur with aging and resulting pharmacokinetic and pharmacodynamic implications, especially with respect to the common chronic conditions and medications that are used to treat them.

MECHANISMS OF AGING

Aging is associated with alterations in physiologic and homeostatic mechanisms. These alterations affect multiple organ systems and contribute to the presence of common chronic diseases.[9–14]

② Aging affects the various organ systems in parallel and this contributes to the majority of older adults having multiple chronic conditions. The aging-associated physiologic and homeostatic alterations that contribute to the pathogenesis of chronic conditions also influence the responsiveness to medications. Therefore, older adults are more likely than younger adults to have medication-associated adverse events (eg, hypotension, hypoglycemia, constipation, delirium, bleeds, cognitive decline, urinary retention, functional decline, and falls).[15,16]

Historically, the exact mechanisms of aging that affect organ function have been difficult to identify. However, the powerful research tools of the current era are revealing some insights into the mechanisms of aging. Comprehensive translational studies have revealed that centenarians have lower chronic disease burdens, lower levels of systemic inflammation, lower frequencies of genetic variants that contribute to chronic disease burdens, and better epigenetic profiles when compared to noncentenarians.[17–23] Therefore, some are considering centenarians as models of healthy aging; other older adults with higher burdens of chronic diseases are being considered accelerated agers. The mechanisms of aging that are being clarified may contribute to the healthcare community's ability to optimize pharmacotherapy for older adults.

HUMAN AGING AND CHANGES IN DRUG PHARMACOKINETICS AND PHARMACODYNAMICS

③ Many theories have been proposed to explain the human aging process. Clinical manifestations of aging include changes in the biochemical makeup of tissues, reduced capacity of body systems, reduced ability to adapt to physiologic stress, and increased vulnerability to disease.[24,25] Interindividual variability in physiology increases with age,[26] as individuals experience aging at different rates along with the development of disease processes and geriatric syndromes (see Chapter e25, "Geriatrics: Assessing Health and Delivering Health Care to Older Adults"). Table e23-1 reviews some common physiologic changes associated with aging, with an emphasis on those changes that can affect pharmacotherapy. For more detailed information, readers are referred to excellent reviews.[24,25]

TABLE e23-1

Physiologic Changes with Aging

Organ System	Manifestation
Body composition	↓ Total body water
	↓ Lean body mass
	↑ Body fat
	↔ or ↓ Serum albumin
	↑ α_1-acid glycoprotein (↔ or ↑ by several disease states)
Cardiovascular	↓ Cardiovascular response to stress
	↓ Baroreceptor sensitivity leading to decreased exercise tolerance
	↓ Cardiac output
	↑ Systemic vascular resistance with loss of arterial elasticity and dysfunction of systems maintaining vascular tone
	↑ Systolic blood pressure and increased risk of arrhythmias
	↓ Compliance of the left ventricle increasing the risk of positional hypotension
Neurological	↓ Size of the hippocampus and frontal and temporal lobes
	↓ Number of receptors of all types and ↑ sensitivity of remaining receptors
	↓ Short-term memory, coding and retrieval, and executive function
	Altered sleep patterns
	↑ Blood-brain barrier permeability
Endocrine	↓ Estrogen, testosterone, growth hormone, thyroid hormone,
	Altered insulin signaling
	Decreased basal metabolic rate
Gastrointestinal	↓ Gastric motility
	↓ Vitamin absorption by active transport mechanisms
	↓ Splanchnic blood flow
	↓ Small bowel surface area
Genitourinary	Atrophy of the vagina with decreased estrogen
	Prostatic hypertrophy with androgenic hormonal changes

	Detrusor hyperactivity and decreased bladder muscle tone may predispose to incontinence
Hepatic	↓ Hepatic mass
	↓ Hepatic blood flow
	↓ Phase I (oxidation, reduction, hydrolysis) metabolism
Oral	Altered dentition
	↓ Ability to taste salt, bitter, sweet, and sour
Respiratory	↓ Respiratory muscle strength
	↓ Chest wall compliance
	↓ Arterial oxygenation and impaired carbon dioxide elimination
	↓ Lung tissue elasticity
Renal	↓ Glomerular filtration rate
	↓ Renal blood flow
	↓ Number of functioning neurons
	↓ Tubular secretory function
	↓ Renal mass
Sensory	Presbyopia (diminished ability to focus on near objects)
	↓ Night vision
	Presbycusis (high-pitch, high-frequency hearing loss)
	↓ Sensation of smell and taste
Musculoskeletal	↓ Skeletal bone mass (osteopenia)
	↓ Muscle mass
	Joint stiffening due to reduced water content in tendons, ligaments, and cartilage
	Altered gait and posture
Skin/hair	Thinning of stratum corneum
	↓ Melanocytes
	↓ Depth and extent of the subcutaneous fat layer

	Atrophy of sweat glands
	Thinning and graying of hair

Data from References 24,27.

Age-associated physiologic changes may result in reduced functional reserve capacity (ie, ability to respond to physiologic challenges or stresses) and reduced ability to maintain homeostasis, thus making the older adult susceptible to decompensation in stressful situations.[24,25,27] Examples of homeostatic mechanisms that may become impaired include postural or gait stability, orthostatic blood pressure responses, thermoregulation, cognitive reserve, and bowel and bladder function. An event resulting in functional impairment may involve an insult for which the body cannot compensate, and relatively small stresses may result in major morbidity and mortality.[24,25,27]

The clinical response to a medication by an individual older adult is the net result of the interaction of a number of complex processes, including PK and PD. Age-related changes in physiology can affect drug PK and PD (see Table e23-1). Concurrent medications and polypharmacy, comorbidities, and frailty also play a role. When applying general knowledge of pharmacokinetic and pharmacodynamic alterations in the older adult to the care of an individual patient in the clinical setting, it is necessary to consider the patient’s overall condition, life expectancy, disease states, and concurrent medications.[28]

Altered Pharmacokinetics

Table e23-2 and the following discussion summarize what is known about the effect of aging on each of the four major facets of PK.[24,28,29] Of interest, when multivariate population pharmacokinetic analyses are conducted, chronologic age by itself seldom is a significant predictor of individual pharmacokinetic parameters (eg, clearance). Aging-associated changes in physiology, such as reduced renal function, are more important predictors of altered pharmacokinetics than is age, per se.

TABLE e23-2

Age-Related Changes in Drug Pharmacokinetics

Pharmacokinetic Phase	Pharmacokinetic Parameters
Gastrointestinal absorption	Unchanged passive diffusion and no change in bioavailability for most drugs
	↓ Active transport and ↓ bioavailability for some drugs
	↓ First-pass metabolism, ↑ bioavailability for some drugs, and ↓ bioavailability for some prodrugs
Distribution	↓ Volume of distribution and ↑ plasma concentration of water-soluble drugs
	↑ Volume of distribution and ↑ terminal disposition half-life ($t_{1/2}$) for lipid-soluble drugs
Hepatic metabolism	↓ Clearance and ↑ $t_{1/2}$ for some drugs with poor hepatic extraction (capacity-limited metabolism). Phase I metabolism is affected more than Phase II.
	↓ Clearance and ↑ $t_{1/2}$ for drugs with high hepatic extraction ratios (flow-limited metabolism)
Renal excretion	↓ Clearance and ↑ $t_{1/2}$ for renally eliminated drugs and active metabolites

Data from References 24, 29, and 30.

Absorption

Most drugs are taken orally; thus, age-related changes in gastrointestinal physiology could affect the absorption of medications. Drug-food interactions, concurrent medication use, and comorbidities affecting gastrointestinal function must also be considered, and frailty may be a better indicator than chronologic age for potential alterations in drug absorption.[31]

Most drugs are absorbed via passive diffusion, and age-related physiologic changes appear to have little influence on drug bioavailability.[24] Nutrients absorbed by active transport, such as vitamin B_{12}, iron, calcium, magnesium and leucine, may have impaired absorption in older adults.[24]

There is evidence for a decreased first-pass effect on hepatic and/or gut wall metabolism that results in increased bioavailability and higher plasma concentrations of drugs such as verapamil and labetalol and reduced bioavailability of some prodrugs such as enalapril and codeine, although the clinical significance of these differences is unclear.[24,31]

Drugs that require an acidic environment for absorption may have reduced extent of absorption in a relatively small proportion of older adults with increased gastric pH due to atrophic gastritis or in those taking proton pump inhibitors and other medications that increase gastric pH.[24,31] The effects of aging on modified-release orally administered dosage forms are not known, although changes in gastrointestinal motility, pH, or gut microbiota due to age, concurrent medications, or comorbidities might affect absorption from some dosage forms in some patients.[31]

Distribution

The distribution of medications in the body depends on factors such as blood flow, plasma protein binding, and body composition, each of which may be altered with age. For example, the volume of distribution of water-soluble drugs is decreased, whereas lipophilic drugs exhibit an increased volume of distribution.[29] Changes in the volume of distribution can have a direct impact on the amount of medication that must be given as a loading dose.

Older adults may also exhibit differences in the distribution of drugs to their sites of action. Tissue perfusion may decrease with aging, slowing the distribution to less highly perfused tissues such as muscle and fat.[32] Small changes in protein binding (decreased albumin and increased α_1-acid glycoprotein) have been documented with aging,[29] but these changes do not generally have a significant effect on drug distribution except for drugs that are highly extracted by the liver, extensively protein bound, or administered intravenously.[24]

Blood-brain barrier permeability may also be altered in older adults, affecting distribution of drugs into the central nervous system. A number of transporters are expressed at the blood-brain barrier endothelium, and dysfunction or reduced expression of transporters can result in greater exposure of the brain to drugs and toxins.[24,33]

Metabolism

The liver is the major organ responsible for drug metabolism, including phase I (oxidative) and phase II (conjugative) reactions. Variations in drug metabolism and consequently drug clearance are a major source of variability in the response to medications in older adults. Hepatic metabolism of drugs depends on liver perfusion, capacity and activity of drug metabolizing enzymes, transfer of drug into the hepatocyte from the blood, and protein binding, all of which may be altered by the aging process.[24] For drugs with high intrinsic clearance (high hepatic extraction ratio) and rapid hepatic metabolism, drug clearance depends on hepatic blood flow (flow-limited metabolism). For drugs with low intrinsic clearance (low hepatic extraction ratio) and slow hepatic metabolism, drug clearance depends on hepatic enzyme activity (capacity-limited metabolism).

Age-related decreases in hepatic blood flow can significantly lower the metabolism of high extraction ratio drugs that undergo flow-limited metabolism. Hepatic blood flow may decline from 40% to 60%, and hepatic clearance of high extraction ratio drugs such as amitriptyline, fentanyl, metoprolol, and morphine may be reduced.[24] The dose of drugs with flow-limited metabolism should be reduced by 50% in older adults according to current recommendations.[24]

Interpreting the effect of age on the metabolism of drugs that undergo capacity-limited metabolism is more complex. Hepatic clearance of capacity-limited drugs depends on the fraction unbound in blood and intrinsic hepatic clearance. Most but not all studies have reported reduced liver size and enzyme content in older adults.[24] Reduced hepatic clearance is thought to be due to reduced liver mass, blood flow, drug transfer, and oxygen supply rather than to reduced function or expression of CYP450 enzymes.[24] Phenotyping may be of more value than genotyping in identifying risk for adverse drug events, and factors such as inflammation, circadian rhythm, epigenetics, and the gut microbiome may play a role in altered drug metabolism in older adults.[34]

Most research on hepatic drug metabolism and aging has focused on age differences in phase I drug metabolism pathways. Generally, phase II metabolic pathways are preserved in healthy older people.[29] Frail older adults, however, experience reduced phase II metabolism. Frailty is a risk factor for declining health status and disability. Although frailty has proven difficult to define, it is characterized by reduced lean body mass, muscle loss, malnourishment, reduced function, and reduced endurance.[35] Frailty is associated with inflammation, which may down regulate drug metabolism and transport.[29]

Elimination

Renal excretion is the primary route of elimination for many drugs and metabolites. Age-related reductions in glomerular filtration are well documented.[35] Changes in kidney function with age may be more associated with hypertension and heart disease than with aging itself, and therefore age alone may not have as great impact on renal excretion of drugs as previously thought.[24]

The estimation of creatinine clearance, although not entirely accurate in individual patients, can serve as a useful screening approximation for the purpose of dosage adjustments. Reduced muscle mass in older adults can result in serum creatinine concentrations within a normal range even though renal function is reduced,[24] so it is essential to estimate creatinine clearance rather than relying on serum creatinine concentrations. Important to remember is that older adults can have reduced muscle mass without low body weights; sarcopenic obesity is a condition in which increased fat stores—which have become common in older adults in recent decades—mask decreased muscle mass and result in the functional disabilities of frailty or sarcopenia (see Chapter e25, "Geriatrics: Assessing Health and Delivering Healthcare in Older Adults"). Cockcroft and Gault[36] created one of the most commonly used equations for adults with stable renal function whose actual weight is within 30% of ideal body weight:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age})(\text{Actual body weight})}{72(\text{Serum creatinine concentration})}$$

$$\text{Creatinine clearance} = \frac{(140 - \text{Age})(\text{Actual body weight})}{72(\text{Serum creatinine concentration})}$$

where age is given in years, actual body weight in kilograms, and serum creatinine concentration in milligrams per deciliter. The resulting creatinine clearance is in units of mL/min. For women, multiply this result by 0.85.

When serum creatinine is expressed in µmol/L, creatinine clearance in units of mL/min can be calculated by the following equation:

$$\text{Creatinine clearance} = \frac{(140 - \text{Age})(\text{Actual body weight})}{0.814(\text{Serum creatinine concentration})}$$

$$\text{Creatinine clearance} = \frac{(140 - \text{Age})(\text{Actual body weight})}{0.814(\text{Serum creatinine concentration})}$$

The Modified Diet in Renal Disease[37] equation and the Chronic Kidney Disease Epidemiology Collaboration[38] equation have become more widely used for estimation of glomerular filtration rate (GFR). The validity of each of these equations for use in estimating GFR in older adults has been advocated and challenged.[39,40] However, dosing guidelines for medications that primarily are renally cleared are often still based on estimated creatinine clearance determined using the Cockcroft and Gault equation, and the current consensus is to continue to use the Cockcroft and Gault equation for renal drug dosing in older adults. New methods based on serum creatinine and cystatin C continue to be developed, so this recommendation may change in the future.[39]

Consensus guidelines for oral dosing of primarily renally cleared drugs in older adults have been developed.[41] Medications to avoid in older adults with creatinine clearance less than 25 to 30 mL/min (0.42-0.5 mL/s) include amiloride, apixaban, dabigatran, duloxetine, fondaparinux, probenecid, rivaroxaban, spironolactone, extended-release tramadol, and triamterene. Medications with recommended dosage adjustments for reduced renal function in older adults include cimetidine, ciprofloxacin, colchicine, dofetilide, edoxaban, enoxaparin, famotidine, gabapentin, levetiracetam, nizatidine, pregabalin, ranitidine, immediate-release tramadol, and trimethoprim-sulfamethoxazole. In making dosing decisions for older adults, it is important to consider guidelines for dosing in renal impairment for drugs with significant renal elimination along with age-related dosing recommendations.

Altered Pharmacodynamics

Age-related changes in PK are well characterized compared to changes in PD. There is a general trend of altered drug response or increased "sensitivity" in older adults. Possible mechanisms that have been proposed include (a) changes in concentrations of the drug at the receptor, (b) changes in receptor numbers, (c) changes in receptor affinity, (d) postreceptor alterations, and (e) age-related impairment of homeostatic mechanisms.[42,43]

Understanding the effects of age on PD has proven to be complex. Differences in PD with age may be due to altered sensitivity (greater change in effect for a given change in drug concentration) but may also be due to differences between younger and older adults in baseline performance or concentrations of drug at the site of action.[42] Most studies of pharmacodynamic differences with age have focused on drugs acting on the central nervous system and cardiovascular system.

Older adults are particularly sensitive to the central nervous system effects of drugs. Changes in brain size and weight as well as changes in neurotransmitter systems have been reported with advancing age. In addition, drugs may penetrate the central nervous system more easily.[42] For example, there are multiple changes to the dopaminergic system with age, including decreased levels of the dopamine transporter, decreased number of dopaminergic neurons, and decreased density of several types of dopamine receptors. These changes are consistent with the increased sensitivity of older adults to the adverse drug effects of antipsychotics.[44] Increased sensitivity to the central nervous system effects of medications in older adults has been demonstrated for benzodiazepines, anesthetic agents, opioid analgesics, antipsychotics, lithium, and anticholinergic medications.[42,43]

Aging is associated with numerous changes in the structure and function of the cardiovascular system that can predispose the older adult to altered pharmacodynamic response to drugs acting on the cardiovascular system. Older adults are more likely to experience orthostatic hypotension as an adverse drug event.[43] Age-related changes in PD have been reported for calcium channel blockers (increased hypotensive and bradycardic effects), beta blockers (reduced blood pressure response), diuretics (reduced effectiveness), and warfarin (increased risk of bleeding), but not with angiotensin converting enzyme inhibitors or angiotensin receptor blockers.[42,43]

SUCCESSFUL AGING

④“Successful”, “positive,” or “active” aging refers to the promotion of physical and mental vitality in later life. Rowe and Kahn[44,45] coined the term *successful aging* and define it as the avoidance of disease and disability, maintaining a high level of mental and physical function and having active engagement with life. Although successful aging encourages health promotion and disease prevention, it may also inadvertently perpetuate ageism by defining success as the responsibility of individual action alone.

There has been much debate and little consensus on a standard definition of what comprises successful aging. Historically, the concept has been studied using either a biomedical or a psychosocial focus. However, simply using a biomedical approach ignores the eventuality of developing disease and decline that lead to mortality and inhibits research and public policy on maintaining personhood while experiencing physical disability. Conversely, simply using a psychosocial approach may provide misleading indicators that do not account for plasticity of the brain and subjective reporting of the personalized factors that constitute success for each individual.[45,46]

For these reasons, we focused our discussion of successful aging using both the perspectives of individual behavior and socio-environmental factors.

Compression of Morbidity, Healthspan, and Optimal Longevity

In recent decades, vast improvements in preventive medicine have altered the landscape of biological aging and longevity. Not only has society experienced an unprecedented increase in longevity, the greater number of years lived is being accompanied by a longer period of activity and health and a postponement of morbidity. Known as “compression of morbidity,”[47] limiting morbidity to a shorter period closer to the natural end of life has become the dominant paradigm for healthy aging, at both individual and policy levels.

The term *healthspan* has emerged to refer to the period of life free of major chronic clinical diseases and disability.[48] Healthspan is a fluid concept that represents dynamic changes in health, the contributions of behavior, lifestyle, and policy that impact health and the role of adjustment and adaptation to changes in health.[49] Taken together, the concepts of compression of morbidity and healthspan have spawned discussion of “optimal longevity” as the general goal of living long and well.[50]

The goal of optimal longevity demands an interactive approach that examines healthy aging behaviors from biopsychosocial perspectives. From a biological standpoint, the field of physiological geroscience has emerged in an effort to increase healthspan by slowing the fundamental biological processes of aging such as inflammation, oxidative stress, mitochondrial dysfunction, impaired proteostasis, and reduced stress resistance.[51]

Of equal importance, optimal longevity is influenced by psychological and social factors that determine how people adjust to aging and whether the individual feels valued societally. Ageism—discrimination based on age—represents a widespread public health crisis, with proven damaging impacts on health and well-being. Negative attitudes about one’s own aging have been correlated with adverse health outcomes, including a 7.5-year decline in longevity,[52] increased risk for chronic disease,[53] perceived ill health,[54] and reduced recovery from illness.[55] Thus, it is imperative that an integrative framework is used to educate and advocate for optimal longevity that addresses aging from biopsychosocial perspectives that incorporate healthy behaviors for both the individual and for the community as a whole.

Primary and Secondary Strategies for Maximizing Physiological Function

Lifestyle, behavioral, and pharmacologic interventions are currently the foremost strategies for enhancing physiological functions during aging. Prevention strategies delay, reduce in magnitude, and/or prevent decline in function, thereby minimizing decreases in functional status and increasing health span. Primary prevention strategies are generally health behaviors that are applied over the course of the lifespan, while secondary prevention strategies are measures that are adopted into a lifestyle approach to maximize health once some degree of physiological dysfunction has occurred in midlife or later.[51] Primary and secondary prevention strategies both include increasing or maintaining physical activity, establishing or maintaining healthy diet and lifestyle behaviors (eg, not smoking, moderate alcohol consumption), and social engagement.

Lifestyle—Physical Activity and Nutrition

Expected changes during biological aging include a loss of muscle mass and strength (sarcopenia), structural and functional changes to skeletal muscle, and neurological and vascular changes that may compromise muscle function. Remarkably, physical activity and exercise are well-established prevention strategies that have demonstrated positive impact on declines in muscle metabolism and function.[56] Further, engaging in physical activity can be the most effective intervention to prevent and in some cases treat chronic diseases that represent the leading causes of morbidity and mortality, such as diabetes mellitus, cardiovascular disease, and cancer.

Two studies examining cardiomyopathy—hypertrophy and fibrosis of the myocardium that causes heart failure—found that exercise was among the most effective interventions for preventing cardiomyopathy.[57,58] Mechanisms included improvement in inflammatory and metabolic profiles as well as exercise-induced changes intrinsic to cardiac tissue.[57] Exercise training can be a countermeasure to impaired immune function secondary to chronic disease, obesity, or advancing age. In general, physical exercise in the form of recreational, occupational, or structured activity is the lifestyle strategy for which there is strongest overall evidence of function-preserving effects, and the highest temporal association with successful aging for those with and without chronic conditions.[59]

Findings from weight loss intervention studies that have included older adults have demonstrated improvements in vascular function, glucose–insulin regulation, endothelial function, and cognition.[60,61] Studies have also observed preserved cardiac diastolic, vascular, autonomic nervous system, and glucose–insulin function, and lower markers of inflammation among older adults on calorically restricted diet,[62] and reduced functional decline among older adults who are restricting their protein and using intermittent fasting (fasting for periods during the week or day).[63] There is an abundance of support or the impact of diet composition on changes in physiological function with aging; specifically evidence that promotes diets high in vegetables, fruits, whole grains, nuts, fish, and “healthy” oils and fats.[62,64] Consumption of this type of diet composition is associated with improved maintenance of motor, vascular, cognitive, and immune function.[64] Consumption of several constituents of these broader dietary patterns including fish, vegetables, olive oils, berries, spinach, grape products and other polyphenols, nuts (walnuts), coffee, green tea, and lower-fat dairy products has been positively associated with increased physiological function during aging.[64]

Socio-environmental Factors and Successful Aging

The importance of social factors on the capacity of individuals to age “successfully’ cannot be overstated. These include risk factors due to lifelong and systemic discrimination based on personal characteristics such as race, ethnicity, gender, sexual orientation, gender identity, and socioeconomic status; interpersonal characteristics such as family structure and living arrangement; and environmental characteristics in neighborhoods, such as access to healthy foods (eg, grocery stores) and healthcare, transportation options, housing, and urban design. A compelling body of evidence has described the powerful role of social factors in shaping health across a wide range of health indicators, populations, and settings.[65]

Formally known as social determinants of health (SDOH; see also Chapter e3, “Social Determinants of Health and Cultural Competency”), these factors have a profound influence in shaping social policy and individual impacts on health. SDOH describe how institutional factors such as income, social support, and access to education influence health and overall well-being. Successful aging and maximizing health span are directly related to the environmental factors and social factors that constitute social determinants of health. The neighborhood or “built” environment encompasses a variety of factors including safety (eg, crime, street lighting, traffic), housing quality (exposure to lead, pollution, allergens), aesthetics (eg, litter, availability of walking paths), accessibility, and amenities. Therefore, a macrolevel approach is necessary in which the view of successful aging is expanded to include contextual influences such as culture, historical time, social structure, institutional forces, and social-relational influences on health and development.[66]

A macrolevel approach is also necessary to take the necessary steps to move the conversation forward about “successful aging” as the sole responsibility of individual choice and behavior to identifying best practices for policy at community levels. The American Geriatrics Society emphasizes the importance of integration of both the health care entities and communities to promote “healthy aging.” Involvement of pharmacists and other health professionals is essential to pursuing these collaborations in the areas of advocacy, education, clinical, and research.[67] Particular attention to cultural differences in both definitions of successful aging and on environmental inequities that may support or prevent successful aging in needed.[66]

ABBREVIATIONS

PK	pharmacokinetics
PD	pharmacodynamics
NHIS	National Health Interview Survey
$t_{1/2}$	half-life
pH	potential of Hydrogen
GFR	glomerular filtration rate
mL	milliliter
min	minute
s	second
µmol	micromolar
L	liter
SDOH	social determinants of health

SELF-ASSESSMENT QUESTIONS

1. As a result of the physiologic and homeostatic alterations associated with the process of aging, older adults are more likely than younger adults to
   - A. Experience adverse effects of medications
   - B. Have fewer chronic disease states
   - C. Be prescribed fewer medications due to pharmacokinetic changes
   - D. Have decrease responsiveness to pharmacotherapy
2. Which one of the following is a physiologic change with aging?
   - A. Increased total body water
   - B. Decreased lean body mass
   - C. Decreased body fat
   - D. Increased serum albumin
3. Which of the following age-related changes contributes to alterations in absorption in older adults?
   - A. Increased first pass effect
   - B. Increased active transport
   - C. Increased gastrointestinal pH
   - D. Increased passive diffusion
4. When looking at the distribution of medications in older adults it is important to consider the _____________ of the agent.
   - A. Acidity
   - B. Lipophilicity

C. Bioavailability

D. High extraction ratio

5. Which of the following agents would be expected to have reduced hepatic clearance in older adults?

A. Lisinopril

B. Oxazepam

C. Digoxin

D. Metoprolol

6. Which of the following should be used for renal drug dosing in older adults?

A. The Modified Diet in Renal Disease equation

B. Bedside Schwarz Equation

C. Cockcroft and Gault equation

D. Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI)

7. Which one of following agents has *not* shown increased central nervous system effects in older adults?

A. Benzodiazepines

B. Opioid analgesics

C. Angiotensin converting enzyme inhibitors (ACE inhibitors)

D. Antipsychotics

8. The avoidance of disease and disability, maintaining a high level of mental and physical function and having active engagement with life is referred to as

A. Desired aging

B. Successful aging

C. Delayed aging

D. Ideal aging

9. All of the following are expected to change during biological aging *except*:

A. Skeletal muscle

B. Neurological function

C. Endocrine system

D. Vascular system

10. ______________ describe how institutional factors such as race, income, social support, and education influence physical health and overall well-being.

   A. Social determinants of health

   B. Lifestyle factors

   C. Personal characteristics

   D. Genetics

11. Women aged 65 years or older have a higher prevalence of which of the following conditions compared with men?

   A. Heart disease

   B. Arthritis

   C. Cancer

   D. Diabetes

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Older adults are more likely than younger adults to suffer from medication associated adverse events including: hypotension, hypoglycemia, constipation, delirium, bleeds, cognitive decline, urinary retention, functional decline, and falls. This is related to the physiologic and homeostatic alterations that are associated with aging.

2. **B.** The body composition of an older adult includes a decrease in total body water, a decrease in lean body mass, an increase in body fat, and a decrease or no change in serum albumin. These are important to recognize as they affect the pharmacokinetics of medications in the older adult.

3. **C.** Contributing factors to age-related changes in gastrointestinal absorption include decrease in active transport, decrease in first pass metabolism, and an increase in gastric pH. This will impact the drugs bioavailability of some agents in older adults.

4. **B.** Distribution of medications depends on blood flow, plasma protein binding, and body composition. Therefore in older adults lipophilic drugs have an increased volume of distribution, which will impact dosing in this population.

5. **D.** Throughout the aging process alterations in hepatic metabolism occur. One example of this is a decrease in hepatic blood flow. Metoprolol, a high extraction ratio drug is greatly affected by this decline in hepatic blood flow. The clearance of metoprolol is reduced from ~34% to 50% or more in older adults.

6. **C.** The Modified Diet in Renal Disease equation and the Chronic Kidney Disease Epidemiology Collaboration equation have been used to estimate GFR in older adult. However, the Cockcroft and Gault equation is currently the preferred equation to provide renal dose adjustment in older adults.

7. **C.** Angiotensin converting enzyme inhibitors do not affect the central nervous system. In older adults drugs may penetrate the central nervous system more readily and an increased sensitivity may result. Agents that have demonstrated increased central nervous system effects in older adults include: benzodiazepines, anesthetic agents, opioid analgesics, antipsychotics, lithium, and anticholinergic medications.

8. **B.** Successful aging is defined as the avoidance of disease and disability, maintaining a high level of mental and physical function and having active engagement with life. Additionally terminology includes successful, positive, or active aging.

9. **C.** Loss of muscle mass and strength are expected changes during biological aging. As a result structural and functional changes to skeletal muscle as well as neurological and vascular changes can compromise the ability of the muscle to function.

10. **A.** Social determinants of health (SDH) describe how institutional factors such as race, income, social support, and education influence physical health and overall well-being.

11. **B.** Women have a higher prevalence of arthritis and asthma, while men have higher rates of heart disease, cancer, and diabetes.

Chapter e24: Geriatrics: Medication Use in Older Adults

Emily R. Hajjar; Lauren R. Hersh; Shelly L. Gray

KEY CONCEPTS

KEY CONCEPTS

① Improving and maintaining functional status is a cornerstone of care for older adults.

② Adverse drug reactions in older adults are common and cause considerable morbidity.

③ Inappropriate prescribing is a major concern and is guided by the Beer's criteria.

④ Polypharmacy can be defined in various ways and is a common occurrence in older adults.

⑤ Underutilization of medications also occurs and can be improved by using the START criteria.

⑥ Pharmacists can play a major role in optimizing drug therapy and preventing adverse consequences of medications in older adults.

⑦ Deprescribing should be considered to reduce medications in older adults.

⑧ Practitioners may consider targeting high-risk older adults to implement comprehensive management strategies.

BEYOND THE BOOK

BEYOND THE BOOK

Read the current American Geriatrics Society Beers Criteria®[13] and discuss the impact of the recommendations on medication use in older adults.

INTRODUCTION

① Pharmacotherapy for older adults can cure or palliate disease as well as enhance health-related quality of life (HRQOL). HRQOL considerations for older adults include focusing on improvements in physical functioning (eg, activities of daily living), psychological functioning (eg, cognition, depression), social functioning (eg, social activities, support systems), and overall health (eg, general health perception).[1] Despite the benefits of pharmacotherapy, HRQOL can be compromised by drug-related problems. The clinical response to a medication in an older adult is the result of the interaction of a number of complex processes, including pharmacokinetics, pharmacodynamics, concurrent medications, comorbidities, and frailty. Age-related changes in physiology can affect drug pharmacokinetics and pharmacodynamics.[2] When applying general knowledge of pharmacokinetic and pharmacodynamic alterations in an older adult in the clinical setting, it is necessary to consider the patient's overall condition, age, diseases, frailty status, and concurrent medications. Prevention of drug-related problems in older adults requires that health professionals become knowledgeable about a number of age-specific issues. To address these knowledge needs, this chapter discusses the epidemiology of adverse consequences of medications in older adults and an approach to optimizing medication use through the provision of a comprehensive geriatric assessment.

ADVERSE CONSEQUENCES OF MEDICATION USE

Although medications used by older adults can lead to improvement in HRQOL, adverse outcomes caused by drug-related problems are considerable.[3] Adverse drug reactions (ADRs) and negative consequences of drug therapy are major threats to the HRQOL of outpatient older adults and account for a significant portion of healthcare expenditures.[4] Estimates are that more than $520 billion was spent in 2016 for prescription-associated morbidity and mortality from nonoptimized medications.[4]

ADVERSE DRUG REACTIONS

② ADRs are a major public health problem for older adults in all settings. ADRs are defined as “a response to a drug that is noxious and unintended and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of disease, or for modification of physiological function” and exclude therapeutic failure and adverse drug withdrawal events.[5] Approximately 9% of hospitalizations in older adults are caused by ADRs, while 16% of older adults experience a significant ADR while hospitalized.[6,7] Moreover, ADRs occur frequently in community-dwelling older adults (10%-35% yearly). Transitions of care are often high-risk times for adverse drug-related events.[8,9] For example, one study found that 19% of older adults experienced an adverse drug event within 45 days of hospital discharge.[8] Some medication classes, such as anticoagulants, antidiabetic agents, and opioids, are especially problematic for causing serious ADRs in older adults and are high priority targets to improve patient safety.[5,10] The use of potentially inappropriate medications (eg, beers criteria drugs) only cause a small proportion of ADRs.[6,8,10] Number of medications is a consistent risk factor for ADRs.[6]

Inappropriate Prescribing

③ Inappropriate prescribing is defined broadly as prescribing medications outside the bounds of accepted medical standards. However, inappropriate prescribing is challenging to define and operationalize. Furthermore, “appropriateness” of prescribing is viewed differently in people with multiple chronic conditions (ie, multimorbidity) or in those who are frail.[11] Inappropriate prescribing is associated with adverse drug events, functional decline, quality of life, healthcare utilization, and increased healthcare costs.[12]

The most widely used explicit criteria are those that include lists of drugs to avoid, or potentially inappropriate medications (PIMs), because the risks of their use likely outweighs any potential benefit. The American Geriatrics Society (AGS) Beers Criteria® (US-based) and Screening Tool of Older People’s Prescriptions (STOPP; European-based) are two common, explicit-based approaches to identify PIM.[13,14] These criteria share some content but also have unique characteristics that are outlined in Table e24-1. Studies conducted in the United States using the Beers criteria have found that up to 29% to 43% of community-dwelling older adults are taking at least one PIM.[15,16] An Irish study found that 46% of older patients used at least one PIM per the STOPP criteria at hospital admission, and a similar extent of use was found in community dwelling older adults.[17,18] A systematic review that examined PIM use by a number of different criteria found that 43% of residents of long-term care facilities were using at least one PIM.[19]

TABLE e24-1

Comparison of American Geriatrics Society Beers Criteria and STOPP Criteria

Criteria	Organization	Number of Criteria
Beers	Criteria are organized into five tables:	
	1. PIMs for all older adults, organized according to organ system and therapeutic category	34
	2. PIMs for some older adults due to drug-disease or drug-syndrome interactions that might exacerbate disease/syndromes (eg, syncope, delirium, dementia, history of falls or fractures, history of gastrointestinal ulcers, urinary incontinence, benign prostatic hyperplasia, heart failure)	10
	3. PIMs to be used with caution (eg, aspirin for primary prevention, dabigatran/rivaroxaban-gastrointestinal bleeding in people >75 years)	6
	4. Potentially clinically important drug-drug interactions that should be avoided (eg, opioids, lithium, phenytoin, warfarin, avoid total of ≥3 CNS active drugs to reduce falls risk)	17
	5. Medications that should be avoided or have dosage reduced with varying levels of kidney function	13
STOPP	1. Organized according to physiological system (11 sections) and include: drugs to avoid, drug–drug, dosing considerations for reduced renal function, and drug-disease interactions	78
	2. A section focused on general concepts that are not medication specific and include: drug prescribed without evidence-based clinical indication, drug prescribed without recommended duration, and therapeutic duplication	3

Data from References 13 and 14.

Assessing the appropriateness of prescribing is complex in older adults with frailty and/or multimorbidity. Many guidelines for disease management focus on a single disease and therefore may have limited relevance to older adults with multimorbidity.[20] Applying disease management guidelines in patients with multimorbidity may contribute to medication burden. Older adults with multimorbidity have varied health outcome priorities and care preferences, which often shift from prevention to symptom relief and maximizing quality of life.[20] A medication used to treat one condition may worsen or interact with control of another condition. Thus, a medication that was once appropriate and beneficial may no longer be providing benefit or align with goals of care. Periodic assessment for opportunities for desprescribing is warranted.

Polypharmacy

④ The term polypharmacy broadly refers to the situation where more medications are prescribed or taken than are clinically appropriate in the context of a patient’s comorbidities and healthcare goals. Polypharmacy has been defined in various ways, but traditionally it has been defined as exceeding an arbitrary number of medications. The most common definition for polypharmacy is the use of five or more medications.[21] While this definition is easy to employ, it does not take medication appropriateness into account.[21,22] For example, an older adult may take 15 medications, and thus have polypharmacy, but all medications may be clinically necessary and appropriate and align with their goals of care. A more clinically relevant concept is distinguishing between appropriate and inappropriate (ie, unnecessary) polypharmacy.[21] Making this distinction is more difficult and time intensive as it as this necessitates a full medication review and assessment.

The use of multiple medications is common and increasing among older adults.[22] In a nationwide survey of community-dwelling older adults, the percentage of the population using five or more medications increased from 30% in 2005 to 36% in 2011. Increased use of dietary supplements, such as herbal products, vitamins, and minerals, adds to the increase in polypharmacy. Approximately 64% of older adults used at least one dietary supplement.[23] Furthermore, the use of unnecessary medications is also common, with 55% to 59% of older outpatients using an unnecessary medication.[24] At hospital discharge, 44% of patients were taking one or more unnecessary medications, with 25% of patients starting the medication(s) during hospitalization.[25] Polypharmacy has been strongly associated with ADRs, risk of geriatric syndromes (eg, falls, cognitive impairment; see Chapter e25, “Geriatrics: Assessing Health and Delivering Healthcare to Older Adults”), nonadherence, diminished functional status, and increased healthcare costs.[21,26]

Underuse

⑤ Underuse is defined as the omission of drug therapy that is indicated for the treatment or prevention of a disease or condition.[27] The percentage of community-dwelling older adults with underuse ranges from 20% to 70%, with higher prevalence among nursing home residents and hospitalized patients.[27,28] The most frequently underused medications in older adults include cardiovascular, anticoagulant, and anti-osteoporotic agents.[27]

Underuse in older populations can occur in the context of “*appropriate*” or “*inappropriate*” decision-making. At times, medications are purposely not used for treatment or prevention. This may be true when life expectancy has been considered carefully (particularly when the time to benefit may exceed the expected time of survival), previous intolerance to a similar medication has been documented, risks outweigh clinical or functional benefits, or when outcomes are not consistent with patient preferences.[29] One study found that healthcare providers had justifiable reasons for underprescribing in 65% of reviewed cases.[30] In instances of potentially “*inappropriate*” underprescribing, decision-making may be based on chronological age alone without recognizing the heterogeneity of medical frailty, functional status, and pharmacotherapy needs of older adults. The fear of contributing to polypharmacy itself may also precipitate underprescribing.[29] Confounding the ability to optimize prescribing trends is the relative absence of data regarding efficacy and safety of medications in older adults.[31] While the literature cites limited and conflicting root causes of underutilization, associative factors include multimorbidity, polypharmacy, dementia, frailty, and social determinants of health.[27,32] Institutionalization stands as a particularly important predictor of underprescribing, particularly in older patients.[28]

The potential impact of underprescribing must be carefully considered. While few studies have directly studied health outcomes associated with underprescribing, there is concern that the criteria used to identify underutilized medications may underestimate harms.[31] Current lines of evidence paint a clear correlation between underprescribing and elevated risk for adverse drug events (ADEs), geriatric syndromes (eg, falls, delirium), increased mortality, and increased hospital admissions and costs to the healthcare system.[28,32] Among nursing home residents with advanced dementia, comfort-promoting medications are largely underused. In nearly one-third of these patients, such medications are used only in the last week of life.[33]

According to a Cochrane polypharmacy review article, there is little evidence to support any single intervention to effectively alter clinical outcomes in the context of underprescribing. Clinical studies have demonstrated some interventions that appear to improve underprescribing trends, although the studies are frequently limited by small sample sizes, poor quality, and heterogeneity.[34] Examples include the use of the comprehensive geriatric assessment, use of clinical pharmacists, physician education, as well as use of the Screening Tool to Alert doctors to Right Treatment (START) criteria.[27,28]

Nonadherence

Even when medication therapy is optimized, patients may not receive the full benefit of therapy if they are nonadherent to medication regimens (see also Chapter e5, “Medication Adherence”). While there is no clear consensus on definition, medication adherence is broadly construed as the extent to which a patient’s medication-taking behaviors correspond with recommendations from a healthcare provider.[35,36] Nonadherence is typically defined as taking less than 80% of prescribed doses of a medication but can also describe delayed prescription fills, reduction of dose strength, reduction of administration frequency, or additional dosing.[37,38] Nonadherence can be further differentiated as intentional versus nonintentional and occurs via noninitiation, suboptimal implementation, or nonpersistence.[37] Nonadherence has been closely linked to treatment efficacy, disease progression, and inappropriate up-titration (with subsequent risk of interactions and adverse drug reactions).[36] Optimized adherence has been linked to avoidance of disease-specific outcomes, increased quality-of-life measures, decreased mortality, and a reduction of healthcare costs, while nonadherence has been linked to at least 10% of hospital admissions.[39]

The prevalence of nonadherence in older adults varies considerably in clinical practice (6%-55%) but frequently registers much higher than in randomized clinical trials required for drug approval.[37] The ability to consistently and reliably identify trends in nonadherent populations is often limited, stemming in large part by inconsistent or unreliable assessment tools. Strategies including drug concentration monitoring, objective measures of disease activity (hemoglobin A1C or blood pressure), pill counts, and patient reporting (which remains the most convenient and frequently used assessment tool).[36–38,40]

While there are many studies exploring those risk factors associated with medication nonadherence, they are frequently outdated, exclude older adults, demonstrate limited generalizability, or do not elicit geriatric-specific causes. In comparison to their younger counterparts, older adults present with higher risk for nonadherence because they are more likely to have complex medication regimens, multiple prescribers, multimorbidity, and higher risks for cognitive impairment.[31,36,39]

While the clinical impact of nonadherence is poorly quantified and understood, resolution of this “adherence gap” provides a strong opportunity to improve patient outcomes and improve system efficiency.[37,41] Increasing the effectiveness of adherence interventions may have a greater impact on the health of the population than any improvement in specific medical treatments.[42] There is a notable gap in the literature regarding high-quality, evidence-based interventions to improve adherence and clinical outcomes among patients.[43] Nonetheless, there are some common-sense approaches to help improve adherence. While it is difficult to provide justification for any single intervention, researchers/clinicians support (1) a clear understanding of patient beliefs, (2) good communication/education, (3) reduction of pill burden, (4) involvement of allied health professionals in clinical care, and (5) adequate follow-up.[37,41]

COMPREHENSIVE GERIATRIC ASSESSMENT TO OPTIMIZE MEDICATION USE

Given that drug-related problems are common, costly, and clinically important, proactive strategies for prevention and management are essential. A number of reviews summarize the effectiveness of pharmacists in improving suboptimal prescribing and medication adherence and reducing ADRs in older adults.[44,45] The following subsections provide an approach to comprehensive geriatric assessment that pharmacists in any practice setting can take to optimize medication use. These approaches may be especially relevant for those providing medication therapy management services under the Medicare Part D program, conducting medication reconciliation, or performing a medication regimen review in a nursing home facility.

History Taking

⑥ Challenges associated with completing medication histories in older adults may make obtaining information about nonprescription agents difficult. Possible barriers include (a) communication problems due to impaired hearing and vision, (b) underreporting (eg, due to health beliefs, cognitive impairment), (c) presence of multiple diseases or use of multiple medications, (d) reliance on a caregiver for the history, and (e) limited access to medical records to confirm findings. Despite these potential barriers, collecting information about nonprescription medications and dietary supplements is a vital component of a complete medication history, and its importance cannot be overstressed.

Asking older adults and caregivers about methods to organize medications is also important. Common strategies that older adults use to organize medications and increase adherence include (1) using a pill box, (2) laying out a whole day’s medications in the morning or at meal times, (3) putting medications in a visible place as a reminder, (4) creating and maintaining a checklist or calendar, and (5) using blister packing or pill packs.[40] Understanding past and current medication management strategies facilitates the pharmacist’s ability to design patient-specific solutions for any problems detected and prevents implementation of previously used but ineffective methods.

Patients and caregivers should be asked about potential risk factors for prescribing problems (eg, using multiple physicians and pharmacies) and issues that may lead to either nonintentional or intentional nonadherence (eg, impaired hearing, vision, or cognition; inability to open safety caps, pay for medicines, or swallow medications; recognition of adverse effects; and perception of health risk).[46] Several approaches to formally assess medication adherence have been reported.[47] A complete drug history should conclude with an inquiry about allergies and current or previous adverse effects, unwanted reactions, or other concerns the patient may have with his or her medications.[48] In addition, it is worthwhile to screen for geriatric syndromes (eg, falls, urinary incontinence, cognitive impairment; see Chapter e25, “Geriatrics: Assessing Health and Delivering Healthcare to Older Adults”) because of their association with medication use.[48]

Assessing and Monitoring Drug Therapy

The first step in assessing medication appropriateness is to compare the patient's medical problem list with his or her drug list. This simple approach can identify the prescribing problems of overuse and underuse. A drug may be considered unnecessary if it does not have an indication per the problem list, is not effective, the risks associated with its use outweigh the benefits, or there is evidence of therapeutic duplication (ie, two drugs from the same class).[14] Though no specific tool may be applicable to all patients, pharmacists may find explicit (criterion-based) or implicit (judgment-based) criteria helpful when evaluating medication regimens for PIM. Explicit measures such as the AGS Beers Criteria and the STOPP tool can be used to quickly identify drugs or medication classes considered harmful in older adults.[13,14] An advantage of explicit criteria to identify potentially inappropriate prescribing is that these approaches require minimal clinical judgment to interpret and thus allow more consistent application. Similarly, three items from the implicit MAI (lack of indication, lack of efficacy, therapeutic duplication) may also aid in detecting unnecessary drug use.[49]

The second step to evaluate medication appropriateness is to determine whether the patient has a chronic condition but is not receiving an evidence-based medication shown to improve outcomes (ie, potential prescribing omissions, underuse). The START criteria may help clinicians identify evidence-based drugs for specific conditions from which older adults would benefit.[14] Next, certain laboratory test results and vital signs should be examined to monitor the efficacy and toxicity of each medication.[50]

Finally, the pharmacist should assess the appropriateness of all remaining medications. A variety of approaches may be used.[51,52] Many tools have been developed to identify potentially inappropriate prescribing, including both explicit- and implicit-based approaches.[53] The implicit-based approaches are judgment based and rely on the clinician's experience to assess an individual patient's medication regimen. Thus, these approaches are highly individualized and may not be applied consistently by different clinicians. The MAI is one implicit standardized measure of prescribing appropriateness that assesses 10 questions that should be asked about each medication with demonstrated validity and reliability (Table e24-2).[49] The MAI addresses the following elements of prescribing: indication, effectiveness, dose, correct directions, practical directions, drug-drug interactions, drug-disease interactions, duplication, duration, and cost. Clinical judgment is required for some criteria; however, the rating process is standardized because of operational definitions and explicit instructions for criteria that increase reliability among clinicians over the typical medication review process.

TABLE e24-2

Medication Appropriateness Index

Questions to ask about each individual medication:

1. Is there an indication for the medication?
2. Is the medication effective for the condition?
3. Is the dosage correct?
4. Are the directions correct?
5. Are the directions practical?
6. Are there clinically significant drug-drug interactions?
7. Are there clinically significant drug-disease interactions?
8. Is there unnecessary duplication with other medication(s)?
9. Is the duration of therapy acceptable?
10. Is this medication the least expensive alternative compared with others of equal utility?

Reprinted, with permission, from Hanlon JT, Schmader KE, Samsa GP, et al. A method for assessing drug therapy appropriateness. J Clin Epidemiol. 1992;45:1045–1051.

Both the MAI and the AGS Beers criteria address drug-drug and drug-disease interactions, two factors strongly associated with ADRs.[13,49] Moreover, these tools cue providers to consider dosing appropriateness, which becomes especially important for renally cleared medications.[13] Directions, therapy duration, and medication cost are other issues to consider during drug-regimen review that could influence adherence and lead to subsequent adverse consequences (Table e24-3).[54]

TABLE e24-3

Examples of Clinically Important Drug-Disease Interactions Determined by Expert Panel Consensus

Disease	Drug
Heart failure	NSAIDs, COX2 inhibitors, thiazolidinediones, dronaderone
Heart failure with reduced ejection fraction	Nondihydropyridine calcium channel blockers
Syncope	Acetylcholinesterase inhibitors, peripheral nonselective α_1-blockers, tertiary tricyclic antidepressants, antipsychotics
Delirium	Anticholinergics, antipsychotics, benzodiazepines, corticosteroids, H2-receptor antagonists, z-hypnotics
Cognitive impairment	Anticholinergics, antipsychotics, benzodiazepines, nonbenzodiazepine hypnotics (eg, zolpidem, zoleplon; also called the “z-hypnotics”)
History of falls	Antiepileptics, antipsychotics, benzodiazepines, antidepressants, z-hypnotics, opioids
Parkinson’s disease	Antipsychotics (except quetiapine, clozapine, pimavanserin), metoclopramide, prochlorperazine, promethazine
Peptic ulcer disease	Aspirin in doses of 325 mg/day or more, NSAIDs
Chronic kidney disease stage IV and higher	NSAIDs
Urinary incontinence in women	Peripheral α_1-blockers

NSAIDs, nonsteroidal anti-inflammatory drugs; COX2, cyclooxygenase 2 inhibitors.

Data from Reference 13.

Documenting Problems and Formulating a Therapeutic Plan

After conducting a comprehensive medication review, the clinician must document any drug-related problems identified, develop a therapeutic plan to resolve them, and establish age-appropriate therapeutic end points, keeping in mind a desirable outcome for a 40-year-old patient may not be reasonable for an 80-year-old one. Because many older adults suffer from multiple chronic conditions, adhering to numerous disease guidelines may complicate medication regimens; these documents typically address diseases independently. One conceptual model to improve prescribing rationales takes into account remaining life expectancy, time until therapeutic benefit, treatment target, medication regimen complexity, patient preference, and goals of care to help clinicians determine whether certain medications should be prescribed or continued.[55]

Deprescribing

⑦ Deprescribing is the systematic process of dose reduction or medication discontinuation. This is an appropriate step when a medication’s risk exceeds its benefit, or medication’s expected benefits no longer align with current patient care goals, preferences, or life expectancy.[55] While there is a conceptual benefit to deprescribing high-risk medications, there are conflicting data with regard to clinical outcomes.[56–58]

When a medication is determined to be appropriate for deprescribing, healthcare providers, patients, and caregivers should discuss the rationale, risks, benefits, and approach to deprescribing each medication to allow for patient preference and shared decision-making.[57] If more than one medication has been identified for deprescribing, clinicians should prioritize the order and determine what approach they will take in the process.[57] Once it has been decided on how the medication will be withdrawn, the tapering plan or medication dosage reduction schedule and reason for withdrawal should be communicated to the patient and caregiver and documented within the health record.[57] Nonpharmacologic approaches should be used to help withdraw medications if appropriate and patients should be appropriately monitored for withdrawal reactions.[57]

One of the risks of deprescribing is creating an adverse drug withdrawal event (ADWE), which is defined as signs and symptoms or signs caused by the removal of a drug. Manifestations of an ADWE may include physiological withdrawal reactions, an exacerbation of the underlying condition for which the medication was being used to treat, or new symptoms caused by abrupt withdrawal.[59] Data on the prevalence of ADWEs in older adults are limited. ADWEs in 38 of 124 male outpatients who had discontinued taking 238 medications.[60]

To prevent ADWEs, it is important to have a plan for reducing the dose or stopping a medication. For instance, some medications may be stopped without any dosage reduction, while others need to be tapered.[59] The most common classes of medications associated with ADWEs are agents that affect the cardiovascular and central nervous systems.[59] To guide deprescribing, guidelines and algorithms are being developed to provide an evidence-based approach to medication withdrawal.[61]

Consulting the Prescriber Regarding Problems and Concerns

To promote continuity of care and a team-based management approach, the pharmacist or other healthcare professional should contact a patient's prescriber regarding concerns that have been detected and documented. When discussing the older patient, the importance of optimizing prescribing *before* implementing strategies to enhance adherence cannot be overstressed. Otherwise, adherence interventions, if effective, may result in harm to patients who suddenly become adherent with medication regimens that may have been titrated inappropriately over time. Similarly, in institutional settings, strategies to reduce medication errors may not improve patient outcomes if prescribing problems are not corrected first.

Counseling and Adherence Devices

When counseling older adults about their medications, it is important to think about general factors that may enhance adherence. Approaches to improving adherence include modifying medication schedules to fit patients' lifestyles, prescribing generic agents to reduce costs, or selecting preferred agents within the insurance formulary to minimize copays for branded medications. In addition, offering easy-to-open bottles, easy-to-swallow dosage forms, and larger type on direction and auxiliary labels may improve medication regimen adherence. When providing medications (particularly new medications or previously used medications that have changes in appearance or directions) to older adults or those with low health literacy, the pharmacist or other healthcare professional should provide both written and oral drug information.[62]

Other strategies to improve adherence include recruiting active patient and caregiver involvement, stressing the importance of adherence and recommending adherence-enhancing aids if necessary (eg, special packaging, medication record, drug calendar, medication boxes, magnification for insulin syringes, dose-measuring devices, and spacers for metered-dose inhalers).[63] In institutional settings, it is prudent to discuss special considerations, such as medications that can be crushed and given via feeding tube and gradual dose reductions of psychoactive medications, with those healthcare professionals responsible for medication administration.

Documenting Interventions and Monitoring Patient Progress

As with the identification of drug-related problems, all interventions provided to rectify issues must be documented. A thorough review of the older adult's medication profile must be repeated routinely and whenever a transition of care occurs (ie, moving from one level of care to another, such as discharge from an acute care setting to home or a nursing facility). During follow-up contact, minimum inquiry should include asking patients if there are questions or concerns regarding medicines and determining whether previously established therapeutic end points have been achieved.

Targeting High-Risk Older Adults

8 In busy practices, the approach outlined above may not be feasible for every patient. Therefore, practitioners may consider targeting patients at high risk for developing drug-related problems.

Studies have identified risk factors for preventable ADRs in older adults. These include higher number of medications, use of specific high-risk drug categories (eg, anticoagulants, antibiotics, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, calcium channel blockers, beta blockers, opioids, oral antidiabetic agents), inappropriate medications, number of comorbidities, and female gender.[6]

CONCLUSION

The number of people age 65 years or older is increasing in the United States and around the world. Improving and maintaining the patient’s functional status and managing the patient’s comorbidities are hallmarks of clinical geriatrics. Adverse consequences of medication use are common in older adults and interprofessional approaches to care are used to improve medication use.

ABBREVIATIONS

ADL	activity of daily living
ADR	adverse drug reaction
ADWE	adverse drug withdrawal event
AGS	American Geriatrics Society
HRQOL	health-related quality of life
MAI	Medication Appropriateness Index
PIM	potentially inappropriate medication
START	Screening Tool to Alert doctors to Right Treatment
STOPP	Screening Tool of Older Persons’ potentially inappropriate Prescriptions

SELF-ASSESSMENT QUESTIONS

1. Which of the following contribute the clinical response to a medication in an older adult?

   A. Pharmacokinetics

   B. Pharmacodynamics

   C. Comorbidities

   D. Concurrent medications

   E. All of the above

2. Which of the following explicit criteria are used to identify potentially inappropriate medications in older patients?

   A. American Geriatrics Society Beers Criteria®

   B. MAI criteria

   C. START criteria

   D. TIMER criteria

3. Which of the following is a common cutpoint to define polypharmacy?

   A. 2

   B. 5

   C. 8

   D. 15

4. Which of the following medications is most likely to be underused in an older adult?

   A. Allopurinol

B. Atorvastatin

C. Escitalopram

D. Levothyroxine

5. In which of the following scenarios would it be most appropriate to omit a recommended treatment?

A. Use of aspirin in a 68-year-old patient with hypertension, dyslipidemia, and diabetes

B. Use of metoprolol succinate in a 70-year-old patient with atrial fibrillation and hypertension

C. Use of rosuvastatin for CVD in a 90-year-old patient with cancer and 6 weeks of life expectancy

D. Use of tiotropium in an 80-year-old patient with chronic obstructive pulmonary disease

6. JJ is an 87-year-old male with moderate neurocognitive disorder. His daughter visits every morning and gives him his medications. She also sets out his evening medications for him to be taken with dinner. Unfortunately, the daughter reports that she finds the evening medications untaken about 3 days/week. When asked, the patient said he tries, but that he just forgets to take his evening medications. What type of nonadherence is this patient exhibiting?

A. Intentional nonadherence

B. Unintentional nonadherence

7. Which of the following are barriers to obtaining a complete medication history in an older adult?

A. Impaired hearing

B. Underreporting

C. Use of multiple medications

D. Reliance on caregiver support

E. All of the above

8. Which of the following items on the Medication Appropriateness Index would define a medication as unnecessary?

A. Complex directions

B. Frequently administered

C. High cost

D. Lack of indication

9. Which of the following is a potential risk of deprescribing?

A. Adverse drug withdrawal event

B. Inappropriate prescribing

C. Polypharmacy

D. Therapeutic failure

10. Which of the following approaches is/are helpful to improving medication adherence in older adults?

A. Medication calendars

B. Written and oral patient counseling

C. Easy to open bottles

D. Caregiver involvement

E. All of the above

11. Which of the following characteristics could help identify an ambulatory older adult at risk for a drug-related problem?

A. Hospitalization within the past 5 years

B. Use of an anticholinergic medication

C. Use of an antihypertensive medication

D. Use of an as-needed medication

12. Which of the following conditions may be exacerbated by the use of an anticholinergic medication?

A. Cognitive impairment

B. Heart failure

C. Hypertension

D. Insomnia

13. Antipsychotics should be avoided in a patient with which of the following?

A. Chronic obstructive pulmonary disease

B. Chronic seizures

C. History of falls

D. Peptic ulcer disease

14. PK is an 87-year-old who presents to her provider with a new complaint of memory loss. Upon questioning, you find that she is taking lisinopril 20 mg PO daily, metformin 500 mg PO twice daily, aspirin 81 mg PO daily, and clonazepam 0.5 mg PO daily. Which of the following is most likely causing her cognitive impairment?

A. Aspirin

B. Clonazepam

C. Lisinopril

D. Metformin

15. In which of the following diseases should NSAIDs be avoided?

A. Heart failure

B. Chronic kidney disease

C. Peptic ulcer disease

D. All of the above

SELF-ASSESSMENT QUESTION-ANSWERS

1. **E.** The clinical response to a medication in an older adult is determined by many things such as the drug and patient's pharmacokinetics, pharmacodynamics, concurrent medications and morbidities, and frailty status.

2. **A.** The American Geriatrics Society Beers Criteria® provide an explicit list of medications that are potentially inappropriate in older adults. The MAI can be used to determine potentially inappropriate medications but are implicit in nature. The START criteria helps to prevent medication omissions, and the TIMER tool is designed to help pharmacists collect information.

3. **B.** The most common cutpoint to definite polypharmacy is five medications. Numeric cutpoints are arbitrarily chosen and do not take medication appropriateness into account.

4. **B.** In older adults, one of the most commonly underused classes of medications is the lipid-lowering agents, including the statins. Other commonly underused classes of medications include antihypertensives, anticoagulants, and bronchodilators.

5. **C.** Omission or underuse of a medication may be appropriate in a patient with limited life expectancy or when the expected benefit of a medication exceeds that of the remaining life expectancy. Underuse may also be appropriate if a patient is intolerant to a medication, when risks outweigh benefits, or the outcomes are no longer consistent with the patient's goals.

6. **B.** Medication adherence is the extent to which a patient's medication-taking behaviors correlate with prescribed treatments or recommendations. This patient would have unintentional nonadherence as they would like to take their medications, but their cognitive impairment prevents them from doing so.

7. **E.** There are many challenges to obtaining a completed medication history in an older adult and include reduced communication due to impaired hearing and vision, underreporting of all medications, presence of multiple diseases and use of multiple medications, reliance on a caregiver for the accurate information, and limited access to medical records to confirm findings.

8. **D.** Lack of indication is one component of the MAI that indicates that a medication is unnecessary. Other components of the MAI that define a medication as unnecessary include lack of efficacy and therapeutic duplication.

9. **A.** One of the risks of deprescribing is causing an adverse drug withdrawal event (ADWE), which is defined as signs and symptoms or signs caused by the removal of a drug. This can include an exacerbation of the underlying condition for which the medication was being used to treat or new symptoms caused by abrupt withdrawal.

10. **E.** A variety of approaches should be used to help improve medication adherence in older adults. See the "Counseling and Adherence Devices" section for more information.

11. **B.** In ambulatory care patients, those at high risk may be identified by use of high-risk medications, use of multiple medications or multiple providers, use of narrow therapeutic range medications, prior history on an ADR, and hospitalization within the past 6 months. See the "Targeting High-Risk Older Adults" section for more information.

12. **A.** Use of anticholinergic medications in an older adult may exacerbate cognitive impairment. For more information on drug-disease interactions, see Table e24-3.

13. **C.** Antipsychotics may predispose a patient to falls. These agents should be avoided whenever possible in patients with a history of falling. For more information on drug-disease interactions, see Table e24-3.

14. **B.** Benzodiazepines are associated with cognitive impairment. For more information on drug-disease interactions, see Table e24-3.

15. **D.** NSAIDs have many drug-disease interactions including heart failure, CKD, and PUD. For more information on drug-disease interactions, see

Table e24-3.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter e27: Critical Care: Pain, Agitation, and Delirium

Caitlin S. Brown; Gilles L. Fraser

KEY CONCEPTS

KEY CONCEPTS

① The primary goal of pain, agitation, and delirium (PAD) management is to provide patient comfort and safety with secondary goals to prevent immediate and long-term adverse physical and psychological outcomes.

② PAD are interrelated and can confound efforts to provide intensive care including mobility, sleep, participation in care, and in shared patient/caregiver decisions about appropriate levels of care.

③ It is important to systematically evaluate PAD with validated tools for timely identification and correction of inciting clinical issues.

④ Preventative measures and nonpharmacologic strategies for PAD management should be initiated as early as possible.

⑤ A multifaceted, interprofessional approach to PAD management impacts care and clinical outcomes.

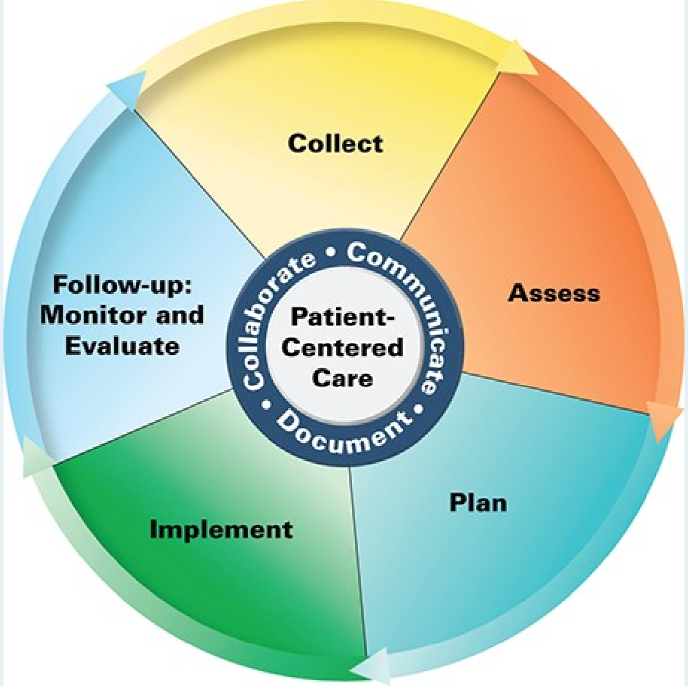
⑥ Pain is an important cause of agitation in the intensive care unit (ICU) and should be assessed and treated before administration of sedatives.

⑦ No proven pharmacologic strategies limit the severity and duration of ICU delirium.

⑧ Sedative choice (dexmedetomidine or propofol) and depth of sedation may have an important impact on patient assessments and outcomes.

PATIENT CARE PROCESS

Patient Care Process* for the Management of Critically Ill Adults with Pain, Agitation, and Delirium



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient-specific characteristics, co-morbidities, allergies, and intolerance to medications
- Psychosocial history (eg, chronic pain, substance misuse, psychiatric diagnoses)
- Symptom specific history (eg, onset, location, duration, chronicity, severity, consequences, and inciting/remediating factors)
- Documented response to interventions for PAD management (efficacy and intolerance)
- Current and past medication use with attention to those associated with agitation or delirium (see Table e27-2)
- Objective data including vital signs, pertinent labs, physical and neurologic evaluations, pertinent imaging studies, short and long-term goals of care including the need for palliative care

Assess

- Presence of PAD symptoms (see Table e27-1)
- Presence of risk factors for PAD (see Table e27-3)
- Symptom resolution using validated PAD assessment tools (see Table e27-4)
- Presence of co-occuring psychological conditions that may confound treatment plan
- Adverse medication reactions or intolerance associated with the use of pharmacologic management of PAD (see Table e27-6)

Plan (collaborate with patient, family, and health professionals)

- Before using medications for symptom relief, ensure that preemptive/preventative strategies are in place, that inciting/prescipitating factor(s) are identified and reversed if possible, and employ nonpharmacologic management strategies (see Table e27-1)
- If necessary, offer pharmacologic management options with identification of treatment goals and a plan to safely terminate therapy when the clinical issue resolves (see Tables e27-1 and e27-5)

- Contingencies should be identified if the initial plan is not successful or not tolerated

Implement

- Educate patient/family and treating team about all elements of the therapeutic plan
- Identify proper starting and incremental dose adjustments along with reasonable assessment durations when using titratable medications.

Follow-up: Monitor and Evaluate

- Resolution of PAD
- Presence of adverse medication reactions
- Monitor withdrawal and resurgence of clinical issues upon discontinuance of medications for PAD management. Implement a dose tapering strategy if appropriate.
- Evaluate the continued need for medications initated in the ICU for PAD management upon discharge from the ICU and hospital and discontinue unwarranted medications

* Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled ‘CAM-ICU Delirium Test’ at the following link: <https://www.youtube.com/watch?v=6WyJ0zL7VkI>. This brief 3-minute video is an overview of a common and valid method of screening for delirium in critically ill adults who are unable to verbalize. This activity is useful to enhance student understanding of the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

Pain, agitation, and delirium are considered the most common clinical conditions confronting critically ill patients and their caregivers. These issues are stressful for patients as well as families and are often precipitated by factors that are frequently seen in the critically ill such as hemodynamic instability, inadequate oxygenation, metabolic derangements, pain, the inability to communicate, immobility, sleep deprivation, the need for invasive instrumentation, and loss of autonomy all occurring in an unfamiliar and threatening environment.

① Short-term patient goals for PAD management include the provision of comfort and safety. It is also important to consider newly recognized long-term outcomes in critical care survivors that affect their quality of life such as the inability to return to baseline physiologic and cognitive function and a high frequency (50%) of unemployment for a year or longer after discharge from the hospital.[1–3] In addition, post-discharge post-traumatic stress disorder (PTSD) and depression are experienced by 7% and 20% to 30% of ICU survivors respectively at one year.[4,5]

All of these outcomes are impacted by our choice of therapeutics for PAD management. For example, the provision of inadequate pain relief can be regarded as inhumane, but conversely, overaggressive opioid therapy continued in the outpatient setting represents an obvious and avoidable risk factor in this era of opioid misuse.[6] The complexity of the pharmacologic and nonpharmacologic management of PAD requires knowledge of the risks and benefits of each option and necessitates a standardized, but flexible evidence-based approach[7] (Table e27-1).

TABLE e27-1

Management of PAD

Assess for presence of PAD	
Pain	≥4 times per nursing shift and as needed with NRS, BPS, CPOT
Agitation/sedation	≥4 times per nursing shift and as needed with RASS and SAS
Delirium	Once per nursing shift and as needed with CAM-ICU and ICDSC
Identify and correct inciting factors when possible	
Establish patient-specific treatment goals	
Nonpharmacologic management	
Pain	Massage therapy; relaxation techniques; cold packs; manipulative medicine
Agitation	Manage pain and discomfort; provide reassurance, support, and empathetic explanations for procedures, diagnostic tests, and diagnoses; avoid excessive noise, immobility, constipation, and physical restraints
Delirium	Correct modifiable risk factors; promote diurnal sleep patterns, and orientation to person, place, circumstance; encourage family visitation; provide cognitive stimulation, mobility efforts; limit sedation
Pharmacologic management	
Pain	Opioids and non-opioids for non-neuropathic; gabapentinoids for neuropathic and post-operative pain; multimodal options
Agitation	Analgosedation; propofol or dexmedetomidine for most patients; reserve benzodiazepines for specific indications
Delirium	Dexmedetomidine for agitated delirium that interferes with weaning from mechanical ventilation; antipsychotics not routinely recommended
Assess response to therapy; if not adequate, consider alternative approach	
Determine plan for withdrawal of pharmacotherapy and transition of care	

BPS, behavioral pain scale; CAM-ICU, confusion assessment method for the ICU; CPOT, critical care pain observational tool; ICDSC, intensive care delirium screening checklist; NRS, Numeric rating scale; RASS, Richmond agitation sedation scale; SAS, sedation agitation scale.

Data from References 7,8.

Although we will be discussing PAD in this chapter as discrete clinical issues, the reader should appreciate that they are inter-related.[9] The interwoven nature of PAD is well demonstrated by a patient with unrelieved pain (a risk factor for delirium) who develops agitation. Dangerous agitation can result in patient harm or injury, but attempts to control these behaviors with sedatives can inadvertently precipitate delirium without addressing the inciting problem of pain.

DEFINITIONS AND CONSEQUENCES OF PAD

Pain

Pain is defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[7] Healthcare providers readily accept and anticipate that ICU patients will have pain associated with surgery, trauma, pancreatitis, or with invasive procedures, but less frequently recognize that pain is provoked by routine ICU care such as repositioning, endotracheal suctioning, and arterial gas determinations.[10,11] Furthermore, it should be appreciated that 50% of patients experience considerable pain at rest, with surgical patients complaining of pain at the site of injury, while medical patients cite back or limb pain.[12] Unrelieved pain is the most common unpleasant memory of ICU survivors and is associated with an acute stress response resulting in hypercatabolic states, increased oxygen demand and the potential for tissue ischemia, impaired wound healing and hyperglycemia.[13–16] Acute pain can also interfere with sleep, mobility and physiotherapy efforts, and pulmonary therapy such as coughing and deep breathing—all impeding the healing process. Longer term issues such as chronic pain syndromes and PTSD have been associated with inadequate analgesia.[13,17]

Agitation

Agitation is described as excess motor and psychological activity that is out of proportion to the evoking stimuli. Resulting behaviors can be either nonpurposeful such as thrashing movements in bed or purposeful and counterproductive such as attempting to dislodge an endotracheal tube or trying to escape the ICU. The most common adverse outcome resulting from uncontrolled agitation is the removal of medical devices.[18,19] Most often this is a mere nuisance such as the removal of a pulse oximeter, but sometimes this represents a legitimate safety risk such as dislodgement of an endotracheal tube, a surgical drain, or vascular access. Uncontrolled agitation in a violent patient may also result in trauma to self and to caregivers. In addition, the excessive sympathetic drive associated with agitation may lead to myocardial ischemia in patients with coronary disease, while blood pressure elevations may be catastrophic in patients with intracerebral hemorrhage or aortic dissection. Disruption of anastomotic sutures is another potential morbid consequence of ICU agitation. Furthermore, agitation may result in longer time in the ICU and on the ventilator exposing patients to a number of iatrogenic risks including nosocomial infections and thromboembolic events.

Delirium

Delirium is an acute onset psychiatric syndrome (caused by an underlying medical condition) characterized by inattention, disorganized thinking, and changes in baseline mental status occurring in a fluctuating manner. Other symptoms of delirium including hallucinations, fear associated with incomprehensible experiences, and extreme emotional feelings can be stressful to patients, families and caregivers.

Three variants of delirium have been identified: hyperactive delirium where patients exhibit motor activity associated with agitation, hypoactive delirium which is associated with a calm demeanor or lethargy, mixed delirium when patients fluctuate between the other two subtypes.[20] Specific definitions and criteria for these subtypes vary, and others have further characterized delirium subtypes by level of arousal (decreased, normal, or increased).[21] The clinical significance and prognostic value of these different delirium subtypes have yet to be defined.

Delirium is strongly *associated* with prolonged hospital stay as well as long-term cognitive impairment similar to that seen in patients with mild Alzheimer's disease or traumatic brain injury, but whether delirium *causes* these worse outcomes is unclear.[2] The effect of delirium on other important clinical outcomes such as ICU length of stay, discharge disposition to a place other than home, dependence on others for activities of daily living, depression, and mortality is unclear. ICU delirium does not seem to be a risk factor for PTSD.[7] It should be emphasized that emotional or psychological distress are the only features of delirium that most agree are causality related.

EPIDEMIOLOGY OF PAD

Pain

①②③ There are many reasons why significant pain is experienced by the majority of patients in the ICU setting, and why unrelieved pain is experienced by more than 40%. Pain is associated with a number of factors, including acute and chronic illness, surgery, trauma, burn injuries, pancreatitis, cancer, comorbidities (arthritis, spinal column issues, chronic pain syndromes), immobility, invasive medical and monitoring devices. Pain also is associated with several routine ICU procedures, including repositioning in bed, catheter and drain insertion and removal (especially chest tube removal and arterial line insertion), endotracheal and tracheal suctioning, and wound care.[8,22] Ineffective pain management is often related to clinician underestimation of its frequency and consequences. Without systematic evaluations, pain may be unrecognized especially in patients who are unable to convey their analgesic needs because of the presence of an endotracheal tube or altered mental status due to their acute illness or sedative regimen.[23,24] Furthermore, the personal and cultural bias of caregivers may serve as barriers to adequate pain relief if they believe that analgesia with opioids may lead to or sustain addiction and misuse. Patients may also play a direct role in inadequate pain relief by not communicating their analgesic needs. They may stoically tolerate pain because of cultural beliefs or because they are concerned about the side effect profile of medications. Interestingly, some patients under-report pain fearing that healthcare provider bias against opioid use will reduce their sense of empathy and alter their care.[13,24]

Agitation

② Some degree of agitation occurs frequently in ICU patients and is a source of discomfort and concern for patients, families, and clinicians.[8] While the most common causes of agitation are pain, delirium, anxiety or substance/prescription withdrawal or intoxication, some patients do not have an obvious reason for their behavior.[25] The multifactorial etiology of agitation along with the potential presence of an unrecognized or undiagnosed baseline psychiatric illness, confounds the ability to provide directed therapy. This is exacerbated by the fact that many patients cannot articulate their needs or concerns because of the presence of an endotracheal tube, depth of sedation, or the presence of encephalopathy.

② Pain must always be considered the primary reason for agitation until it is ruled out. This is best evaluated by patient self-report and with validated behavioral pain scales if self-report is not possible.[7] Psychiatric illness, psychoactive drug use (prescription and other substances including alcohol), cognitive impairment, metabolic derangements, along with kidney and liver failure predispose patients to ICU agitation.[26] Many medications and nonprescription substances are associated with agitation as a result of withdrawal or acute toxicity (Table e27-2). Extreme anxiety can lead to agitation especially if it is provoked by unexpected or unexplained therapeutic or diagnostic interventions. The apprehension of not knowing the outcomes of an acute illness can be an important cause of anxiety and agitation in susceptible patients and reinforces the need to continually inform patients about their health status and planned interventions.

TABLE e27-2

Common ICU Medications Associated with Agitation and Delirium

Category	Medication	Agitation	Delirium	With Use	With Withdrawal
Antibiotic					
	Cefepime[27,28]	x	x	x	
	Macrolide[29]	x		x	
	Quinolones[29–31]	x	x	x	
	Voriconazole[29]		x	x	
Anticholinergic					
	Diphenhydramine[32]		x	x	
Anticonvulsant					
	Gabapentin[33]	x			x
	Levetiracetam[34]	x		x	
	Pregabalin[35]	x			x
Antidepressant					
	Amitriptyline[36]	x	x		x
	SSRI[36,37]	x	x	x	x
	SNRI[36,37]	x	x	x	x
Gabaminergic					
	Benzodiazepines[7,36]	x	x	x	x
Miscellaneous					
	Corticosteroids[38]	x	x	x	
	Digoxin[39]	x	x	x	
	Ketamine[36]	x	x	x	x
	Psychoactive medications[7,36]	x	x	x	x

SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin-norepinephrine reuptake inhibitor.

Illness related factors contributing to ICU agitation include acute respiratory failure, fever, acidosis, hypoxemia, sepsis, other infectious diagnoses, and hyperactive or mixed delirium from a number of causes. In addition, neurologic insults resulting from strokes or traumatic brain injury, malignancies, and seizures can provoke agitation.

Possible environmental factors leading to agitation include sleep deprivation, excessive noise or light, mechanical or noninvasive ventilation, the inability to communicate, loss of control over body functions, thirst, and the presence of intravascular and drainage catheters and feeding tubes. Use of restraints is often necessary to ensure patient safety, but these devices also contribute to agitation.[26] Systematically assessing and addressing these causes of agitation is the first step in providing comfort in the ICU and should proceed prior to or contemporaneously with medication use.

Delirium

Delirium is common in ICU patients, occurring with an estimated frequency between 20% and 90%.[40] The actual incidence of ICU acquired delirium may be lower than previously reported in part related to changes in critical care practices that avoid deep sedation and facilitate physiotherapy and mobility interventions.

Evaluating risk factors for delirium in the ICU is complex due to heterogeneity in the underlying diseases and their severity prior to delirium onset, competing events that may preclude delirium detection, the high frequency of multiple delirium risk factors being present, and varying detection rules for delirium and risk factors. Delirium risk factors have been categorized in different ways, but perhaps the most helpful approach is to identify those that are correctable (eg, medication selection, depth of sedation) and should be the focus of our interventions, compared to those that cannot be altered (eg, age, severity of underlying disease).[41] Table e27-3 lists these risk factors, identifying a small number of correctable or preventable factors, including infections, metabolic derangements such as hypoglycemia, hyponatremia, hyperammonemia, acidemia, and benzodiazepine administration.[41] Besides benzodiazepines, many other medications may increase the risk for delirium. It is also important to emphasize that intentional or inadvertent discontinuance of some medications or substances may contribute to delirium (Table e27-3).

TABLE e27-3

Risk Factors for ICU Delirium

Predisposing Risk Factors[a]	Quality	Level of Evidence
Age	High	Strong
Dementia	High	Strong
Hypertension	High	Strong
Acute Physiologic Assessment and Chronic Health Evaluation (APACHE) score	High	Strong
Emergency surgery	High	Strong
Organ system failure	Positive	Moderate
Polytrauma	Mixed	Strong
Potentially Correctable Factors		
Coma	High	Strong
Delirium previous day	High	Strong
Mechanical ventilation	Mixed	Strong
Metabolic acidosis	High	Strong

[a] Additional reported factors which were inconclusive or with only weak evidence on systematic review: gender, alcohol or nicotine use, American Society of Anesthesiologists physical status, cardiac disease, acute respiratory disease, impaired kidney function, admission to medical team, fever, anemia, bilirubin or urea elevation, hyper-/hyponatremia, room without daylight.

Data from Reference 42.

④ Environmental risk factors are also potentially correctable risk factors for delirium, including forced immobility, restraint use, the presence of invasive catheters, excessive noise and lighting, omission of common orientation aids such as clocks, calendars, eyeglasses, hearing devices, and natural circadian light. It is uncertain if sleep deprivation is a cause or consequence of delirium, but this common ICU issue should be addressed.[7]

Identifying specific patients at high risk for delirium may provide an opportunity to focus on preventative strategies and assessment plans. Two delirium prediction tools, E-PRE-DERILIC and PRE-DERILIC have been developed and tested for validity. They assess age, acuity of illness indicators, urgency of admission, infection, coma, sedation, morphine use, urea or blood urea nitrogen, metabolic acidosis, alcohol use, mean arterial blood pressure, use of corticosteroids, respiratory failure, and other risk factors. E-PRE-DERILIC is administered at the time of ICU admission, whereas PRE-DERILIC is assessed within 24 hours of ICU admission. E-PRE-DERILIC is preferred by clinicians because it is easier to use, but PRE-DERILIC may have better predictive capabilities.[43]

PATHOPHYSIOLOGY OF PAD

Pain

Pain is a complex symptom and can be classified as acute, chronic, or acute on chronic.

A complex physiologic cascade results in the detection, transmission, and perception of pain initiated by stimulating nerve transmission and release of inflammatory substances (substance P, bradykinin, histamine, prostaglandins, serotonin). These nerve impulses travel to the spinal cord where both excitatory (glutamine and aspartate) and inhibitory γ- aminobutyric acid (GABA) neurotransmitters help define the individual's perception of the stimuli. Ultimately, endogenous substances within the brain such as endorphins and enkephalins modulate the pain signal.[44] The complexity of these pathways help explain the great variability in an individual patient's perception and tolerance of painful events (see Chapter 79).

Agitation

There are no established pathophysiologic pathways to explain adverse behavioral changes associated with agitation, but excessive sympathetic activity, changes in pain sensation or hypothalamic-pituitary-adrenal axis dysfunction have been implicated.[45]

Delirium

The underlying pathophysiology of delirium is incompletely understood. Though classically described as an imbalance of brain neurotransmitters (particularly choline, dopamine, and serotonin), this represents an oversimplification. Other proposed pathways for delirium include a direct neurotoxic effect of inflammatory cytokines, derangement of the blood brain barrier, and neuronal dysfunction, ultimately leading to the behavioral and cognitive symptoms common to this disorder.[46]

ASSESSMENT TOOLS AND THERAPEUTIC GOALS

Pain

③ Pain management begins with a careful assessment of its source, duration and severity, but this may be difficult in ICU patients. ICU patients are often unable to communicate their analgesic needs; however, despite these barriers, all ICU patients should have their pain assessed with a validated scoring tool at least four times during a nursing shift as well as before and after the administration of an analgesic medication.[8] Online sources for selected PAD assessment tools are provided in Table e27-4. The systematic assessment of pain decreases significant pain by nearly 50%, and since pain is more readily identified as the reason for agitation, inappropriate sedative use is decreased by 30%.[23,47] Reductions in the duration of ventilation and length of ICU stay have also been associated with pain management strategies that include embedded pain assessment protocols.[47,48]

TABLE e27-4

Online Sources for Selected PAD Assessment Tools

Tool	Website
Pain (CPOT, BPS)	http://www.icudelirium.org/pain.html
Agitation/sedation (RASS, SAS)	http://www.icudelirium.org/sedation.html
Delirium (CAM-ICU, ICDSC)	http://www.icudelirium.org/delirium/monitoring.html
Delirium risk factors/causes	http://www.icudelirium.org/terminology.html

BPS, behavioral pain scale; CAM-ICU, confusion assessment method for the ICU; CPOT, critical care pain observational tool; ICDSC, intensive care delirium screening checklist; RASS, Richmond agitation sedation scale; SAS, sedation agitation scale.

Patient self-report is regarded as the gold standard to evaluate pain with the numeric rating scale (NRS 0-10) representing the most commonly used metric. A score greater than 3 (on an 11 point scale) represents significant pain. For patients unable to communicate, but who retain motor activity (ie, no neuromuscular blockade or neuromuscular disease), validated behavioral pain scales such as the Critical Care Pain Observation Tool (CPOT) or the Behavioral Pain Scale (BPS) should be used.[7] Though these two pain scales are similar (they evaluate facial expression, body movement, muscle tension, and compliance with the ventilator), they are scored differently and thresholds to determine significant pain reflect these differences. It should be noted that patient behaviors such as facial expression, eye closure, and muscle rigidity are blunted with increasing levels of sedation emphasizing the importance of maintaining light sedation to accurately assess pain.[49,50]

Surrogate pain assessments by family members may provide additional information for patients unable to self-report. Pain is correctly identified in most cases, but the severity of that pain is often overestimated by families. Nurses correctly identify pain with a similar accuracy as family members, but interestingly, they tend to underestimate its severity.[51] This highlights the importance of providing light sedation to facilitate more accurate estimates of analgesic need directly from patients, and when self-report is not possible, to utilize several sources of information.

Vital signs are commonly used as a measure of pain or discomfort, but this practice should be discouraged since elevations in heart rate, respiratory rate, and blood pressure can occur in response to non-pain-related stimuli such as fear, anxiety, and other stressors in the ICU. Furthermore, they can be modulated by many therapeutic interventions including beta-blockers, calcium channel blockers, and sympathomimetic agents. Increased vital signs should primarily serve as cues for further pain evaluation using validated scoring tools, and normal vital signs should not preclude the possibility of pain.[8]

Agitation/Sedation

④ Similar to pain, the first step to limit agitation is through systematic assessments with validated scoring tools performed at least four times during a nursing shift.[8] This practice may result in a 33% reduction in potentially dangerous agitation through early identification and correction of stressful patient conditions.[23] If agitation persists and requires the administration of sedative medications, these same assessment tools can be used to monitor the response to therapy and to serve as a means of identifying and communicating sedation goals to all caregivers.

At least 11 sedation scales have been proposed for use in the ICU, but 2 are recommended by the SCCM 2018 PADIS guidelines based on a psychometric analysis of their reliability, validity, feasibility, and utility; RASS and SAS (Table e27-4).[52] For most patients, a light level of sedation provides comfort, allows wakefulness, and enables patient self-report of pain and participation in delirium assessment. A SAS score of 4 and RASS of −1 have been shown to best predict light sedation..[53] Treatment goals should include the ability for patients to comfortably and safely participate in their care as well as in decisions about that care. This degree of sedation also facilitates effective pulmonary toilet, liberation from mechanical ventilation, participation in physiotherapy and mobility, repositioning, and other nursing interventions. Furthermore, avoiding deep sedation decreases mortality, ICU and hospital lengths of stay, and the need for tracheostomy and diagnostic testing for unexplained mental status changes.[44] In fact, the provision of light sedation administered within the first 48 hours of mechanical ventilation may have a favorable impact on mortality, delirium frequency, and ease of extubation.[45]

It should be recognized that deep sedation (RASS −3 to −5 or SAS 1-2) may be necessary for specific subsets of ICU patients; such as those with status epilepticus, receiving neuromuscular blockade, having elevated intracranial pressure, experiencing tenuous respiratory function despite mechanical ventilation, and to protect complex surgical wounds. Since the clinical exam is likely not helpful to guide deep sedation titration once patients are unresponsive, the PADIS guidelines recommend that therapy be monitored with processed EEG-based technology such as the bispectral index (BIS).[7] Appreciation of the potential influence of electromyographic (EMG) artifact is critical to the interpretation of the BIS findings.[54]

Two different sedation strategies for mechanically ventilated ICU patients are promoted by SCCM, ACCP and the ATS.[7,55] The first approach is to consistently provide light sedation, defined as the ability of patients to attend to 3 of 5 commands such as wiggle toes, display two fingers, open eyes.[8,56] Another approach allows deeper sedation coupled with a daily “wake up” when sedation is interrupted at least once daily in order to assess mental status and is often linked with a spontaneous breathing trial. Both of these approaches appear effective, but the first allows patients to communicate and participate in their care throughout the day rather than on an intermittent basis.

Delirium

③ The PADIS guidelines suggest that best practice includes systematic delirium assessments with validated tools at least twice daily.[7] Theoretical benefits include identification of hypoactive delirium (which is often missed clinically), timely recognition and correction of inciting factors for delirium (potentially leading to improved outcomes), and the opportunity to discuss delirium’s distressful symptoms with patients and their families.

At least five delirium assessment tools are available for the ICU. However, the CAM-ICU and ICDSC are recommended based on favorable psychometric testing (validity, reliability, feasibility, impact on patient outcomes; Table e27-4).[8] Despite improvements in delirium identification with these tools, their effect on clinical outcomes remains unclear. This may relate to the fact that currently available tools to detect delirium confound these assessments since they cannot discriminate between physiologic and pharmacologic changes in mental status.[7] It is important to note that patients with initial positive delirium assessments that resolve after interrupting sedation have clinical outcomes similar to those who never test positive for delirium. In fact, rapidly-reversible sedation-related delirium may represent sedation and not delirium,[57,58] and it emphasizes the value of performing delirium assessments when patients are as wakeful as possible and certainly after sedation interruption.

TREATMENT

The primary pharmacotherapy recommendations for PAD and the corresponding PADIS guidelines are presented in Table e27-5.

TABLE e27-5

Selected Pharmacotherapy Recommendations from the 2018 PADIS Guidelines

Recommendation and Guideline Year	Recommendation Grade[a]
Pain	
Use multimodal approach to decrease opioid exposure	Conditional
Use enteral gabapentin, pregabalin, or carbamazepine with opioids for neuropathic pain	Strong
Use enteral gabapentin, pregabalin, or carbamazepine with opioids for pain after cardiovascular surgery	Conditional
Use an opioid, at the lowest effective dose or NSAID as an opioid alternative for procedural pain along with nonpharmacologic interventions	Conditional
Use an assessment-driven, protocol-based stepwise approach for pain management	Conditional
Agitation/sedation	
Use with an assessment-driven, protocol-base, stepwise approach for sedation management	Conditional
Titrate sedatives to light (vs deep) sedation	Conditional
Propofol or dexmedetomidine are preferred over benzodiazepines for sedation	Conditional
Delirium	
Do not use haloperidol or atypical antipsychotics to prevent delirium	Conditional
Do not routinely use haloperidol or atypical antipsychotics to treat delirium	Conditional
Use dexmedetomidine for delirium in ventilated patients where agitation is precluding weaning or extubation	Conditional

[a] Strong recommendation: applies to almost all patients, is based on moderate to high quality data where the benefits clearly outweigh the burdens;

Conditional recommendation: applies to most patients but with significant exceptions based on context using data that are conflicting, low quality, insufficient or involve limited patient populations where there may be a close balance between benefits and burdens.

Data from Reference 7.

General Concepts

Pain

④ and ⑤ Many *nonpharmacologic* interventions have been proposed to reduce pain with varying results, but few have been studied rigorously. Nonpharmacologic approaches are generally safe, not expensive to implement, and may complement pharmacologic management options.[7] The higher degree of pain that most ICU patients experience will, however, often require additional pharmacologic treatment.

The choice of *pharmacologic* agent(s) for pain relief is complex. A number of patient factors must be considered including the type of pain (nociceptive vs neuropathic, chronic vs acute), its intensity (mild to severe), precipitating factors (present at rest or only with specific events such as suctioning, repositioning, inserting or removing medical devices), its duration (prolonged vs limited), prior patient response to interventions, the status of organs responsible for medication metabolism and clearance, pulmonary function, hemodynamic stability, required onset and offset for pain relief, evidence for tolerance to analgesic choice, the need for IV administration, consideration of potential drug interactions and adverse medication reactions, and whether the patient requires continuous ventilator support.

Analgesic agents can be administered in a variety of ways. IV administration as a continuous infusion is useful for sustained analgesia, while intermittent injections are appropriate for procedural, predictable, or short-lived pain. Enteral administration should be reserved for patients not requiring analgesic dose titration. Opioid transdermal patch formulations may be helpful in stable patients once analgesic requirements are established, but because their onset is delayed and medication absorption may be increased in febrile patients, they are not recommended in critically ill patients. For patients with intact motor function who are sufficiently wakeful, patient-controlled analgesia represents another viable option for analgesic delivery. Nonintravenous regional or neuraxial strategies may be useful in a variety of pain syndromes and are usually the domain of anesthesiologists.

⑥ An analgesia-first (the administration of an analgesic agent *before* sedation administration) or analgesia-based (the administration of an analgesic agent *instead* of a sedative) strategy has been suggested in the 2013 PAD and 2018 PADIS guidelines.[7,8] This approach is based on the fact that pain is common in ICU patients, is a major reason for agitation, and that a step-wise protocol-based intervention improves pain relief, limits sedation requirements, decreases dependency on mechanical ventilation, and may shorten ICU length of stay.[59] An analgesia-first approach is not appropriate for agitation due to substance withdrawal (except if opioid related), any medication-induced condition such as serotonin syndrome, neuroleptic malignant syndrome or encephalopathy, status epilepticus, or any other condition with a clear and reversible etiology best treated with a directed management strategy.

Because the opioids are associated with a number of important adverse medication reactions as well as the perceived risk of addiction and misuse,[60] a multimodal approach is suggested.[7] A multimodal approach (concurrent medication options with different mechanisms of action) offers the promise of improving analgesic response while limiting exposure to the opioids and their complications.

Sedation/Agitation

② As discussed above, management strategies must consider and address pain as the most common cause for ICU agitation while simultaneously seeking to identify and treat other underlying reasons for agitation. If pain or discomfort is not present or if the provision of analgosedation is not adequate, traditional sedative agents may be required. Therapeutic choices for agitation must be driven by patient context. Clinicians should consider previous patient response to interventions, the status of organs responsible for medication metabolism and clearance, hemodynamic stability, neurologic function, respiratory status, home medication and substance use, prior or acquired psychiatric diagnoses, the required onset and offset for behavioral control, the need for IV administration, the degree of ventilator support, and consideration of potential drug interactions and adverse medication reactions. Commonly used analgesics and sedative agents that are administered as infusions are presented in Table e27-6.

TABLE e27-6

Common ICU Analgesics and Sedatives Administered as Infusions

Drug	MOA	Dosing Range[a]	PK/PD properties	ADR and Special Populations	Useful Information
Analgesics					
Fentanyl	µ agonist	25-200 mcg/h; LD = 50-100 mcg	1-2 min onset; 2-4 h half-life; CYP3A metabolism; no active metabolites	Serotonin syndrome; caution with SSRI and SNRI	Rapid onset and offset; useful in kidney disease; less hypotension vs morphine; interaction with CYP3A metabolized drugs (midazolam)
Hydromorphone	µ agonist	0.5-4 mg/h; LD = 0.5-2 mg	5-10 min onset; 2-3 h half-life; glucuronidation; neurotoxic metabolite	Rare neurotoxicity due to metabolite accumulation in kidney disease	Slower onset than fentanyl, but longer duration; no CYP interactions and no serotonin syndrome
Morphine	µ agonist	2-30 mg/h; LD = 2-5 mg	5-10 min onset; 3-4 h half-life; demethylation and glucuronidation; active metabolites	Hypotension; accumulation of active metabolites in kidney disease	Venodilation from histamine release
Remifentanil	µ agonist	0.5-15 mcg/kg/h; LD = 1.5 mcg/kg	1-3 min onset; 3-4 min half-life; esterase metabolism; no active metabolites	Allows frequent evaluations of neurologic function	Drug clearance unaffected by organ dysfunction; use IBW to dose obese patients; costly
Ketamine	NMDA receptor antagonist	0.05-0.4 mg/kg/h; LD: 0.1-0.5 mg/kg	1 min onset; 2-3 h half-life; demethylation; active metabolite	Possible hypertension; psychological disturbances	Does not interfere with respiratory function; useful for opioid tolerant patients
Sedatives					
Dexmedetomidine	Central α2 agonist	0.2-1.4 mcg/kg/h	5-10 min onset; 3 h half-life; CYP2A6 metabolism and glucuronidation; no active metabolites	Bradycardia and hypotension	Does not interfere with respiratory function; allows “cooperative sedation;” opioid sparing properties; less delirium than midazolam
Midazolam	GABA agonist	1-5 mg/h; LD = 1-5 mg	2-3 min onset; 3-11 h half-life; CYP3A metabolism; active metabolites	Delirium; context-sensitive half-life	Less hypotension than propofol or dexmedetomidine; allows deep sedation and amnesia; CYP3A interactions
Propofol	GABA agonist	5-50 mcg/kg/min	1-2 min onset; 3-12 h half-life; CYP2B6 and CYP3A metabolism; no active metabolites	Hypotension; PRIS; hypertriglyceridemia; pancreatitis	Allows easy goal titration and neurologic evaluations; can provide deep sedation with amnesia; no analgesia; interacts with midazolam

ADR, adverse drug reaction; cooperative sedation, ability to participate in care and follow commands; CYP, cytochrome P450; GABA, γ- aminobutyric acid; h, hour; IBW, ideal body weight; LD, loading dose; MOA, mechanism of action; min, minute; NMDA, N-methyl-d-aspartate; PK/PD, pharmacokinetic/pharmacodynamic; PRIS, propofol related infusion syndrome; SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin norepinephrine re-uptake inhibitor.

[a] Typical dosing range for adult ICU patients; analgesic dosing requirements for pain relief may exceed these recommendations as will sedative dosing requirements to produce deep sedation

Data from Reference 8.

Sedative agents can be administered in a variety of ways. IV administration as a continuous infusion is useful for sustained agitation while intermittent injections are appropriate for procedures or acute control of agitation. Some medications, such as lorazepam and clonidine may be given via enteral feeding tubes using available enteral formulations. It should be appreciated and emphasized that not all ICU patients require sedation.

Delirium

⑦ The mainstay of delirium management is to identify and correct contributing factors. These risk factors are generally grouped according to the ability to be corrected or treated (Table e27-3). There is no evidence supporting pharmacological interventions to prevent ICU delirium, even in high risk patients.[61,62] Furthermore, there is little evidence demonstrating clinical improvement with pharmacological treatment of delirium (except perhaps related to alcohol withdrawal).[63] Symptom control with antipsychotics or dexmedetomidine for agitated patients may be reasonable.[7]

Nonpharmacologic Management

Pain

④ Initial pain management strategies should be directed at the source of the discomfort and may include nonpharmacologic strategies such as repositioning in bed, adjustment of endotracheal or chest tube placement, or stabilization of fractures. In addition, nontraditional medical approaches such as manipulative medicine may be helpful. Other beneficial nonpharmacologic strategies include massage therapy, music (with particular attention to patient preference), relaxation techniques, and cold packs (the latter two are helpful in the setting of procedural pain management).[7] If these strategies are not adequate, pharmacologic options should be employed.

Agitation

②④ Since stress is a primary reason for agitation, its source should be identified as quickly as possible. It is reasonable to assume that pain and discomfort are often present and nonpharmacologic strategies to limit these conditions should be the first considered. Survivors of the ICU experience have reported that loss of control over basic activities of daily living is both frightening and stressful. Caregiver reassurance, support, and an empathetic explanation for tests, procedures, and care plans, along with frequent family visits represent personal approaches that can reduce the psychological stress associated with being critically ill. Other modifiable stressors that should be addressed include dyspnea, excessive noise, constipation or distended bladder, and immobility. The low risk, low cost features of nonpharmacologic interventions for ICU agitation support their use even in the absence of supporting evidence.[7]

Despite the lack of evidence supporting any clinical benefit, physical restraints have been traditionally been used in combative patients to prevent medical device removal, avoid falls, and to protect staff. However, restraints may paradoxically increase the risk for all of these issues and may contribute to delirium. Routine placement of restraints should be discouraged.[7]

Delirium

⑤⑦ The initial management of delirium should involve a thorough evaluation and correction of modifiable risk factors including metabolic derangements, infections, medication use and withdrawal syndromes, and brain injury.[64] A multicomponent nonpharmacological approach for delirium prevention and treatment centers on consistent patient orientation to time, place, person and circumstance by caregivers and family. These approaches may include access to calendars, clocks, family photos, and daylight, the provision of eyeglasses and hearing devices, promotion of diurnal sleep patterns along with limiting napping during daylight periods, cognitive stimulation, mobility efforts, and the limitation of sedation. When used in a multicomponent, bundled fashion, these interventions reduce the incidence and duration of delirium and are recommended by the PADIS guidelines.[7]

Pharmacologic Management

Pain

Opioids

Opioids are the most frequently used medications for pain relief in the ICU because of their potency, ease of administration through a variety of routes (eg, enteral, rectal, transdermal, IV, epidural), caregiver familiarity, and because they have some sedative properties. Opioids typically serve as the foundation for analgosedation.

All opioids share similar pharmacologic properties and interact with μ-opioid receptors to inhibit the release of inflammatory and excitatory mediators resulting in disruption of nerve signal propagation and diminished activity of nociceptors. Most opioids also have N-methyl-d-aspartate (NMDA) receptor agonist properties which paradoxically increase nociceptor stimulation and may result in the development of tolerance to their analgesic activity. Distinctions between the opioid medications are largely (though not entirely) related to their pharmacokinetics, pharmacodynamics, and expected adverse medication reactions (Table e27-6). These differences can help guide the optimal choice of opioid for a specific patient. For example, if rapidity of action is desired, IV fentanyl with its high degree of lipophilicity would be preferred whereas hydromorphone might be a better choice if a longer duration of action required. Morphine administration should be avoided for patients with kidney disease because of accumulation of its renally-cleared active metabolites.[8]

Opioid-Associated Adverse Medication Reactions

Opioid therapy is associated with diverse and significant adverse medication reactions. Constipation is common to all opioids and results from stimulation of gastrointestinal μ receptors leading to inhibition of gastric emptying and delays in gastrointestinal transit times in both small and large intestines. As many as 80% of opioid treated patients will experience constipation.[65] This is often associated with discomfort and delays achievement of nutritional goals. Opioid-induced constipation is also associated with inadequate oxygenation, hypotension, prolonged ICU length of stay and even mortality.[66] Pre-emptive management with routine administration of stool softeners and stimulant cathartics may be effective, but if they are not sufficient, a step-wise introduction of other modalities such as lactulose, polyethylene glycol, stimulant suppositories or enemas is recommended. Methylnaltrexone, a peripherally acting μ receptor antagonist is often effective when initial strategies fail.[64] Dosing is weight based and dependent on kidney function, and since methylnaltrexone does not cross the blood-brain barrier, opioid-mediated pain control is maintained. Methylnaltrexone is contraindicated in patients with bowel obstruction because of the risk for intestinal perforation.[67]

Respiratory depression is also common to all opioid medications and can interfere with efforts to wean from mechanical ventilation. Risk factors for opioid-induced respiratory depression include age over 60 years, opioid naivety, pulmonary or cardiac dysfunction, pre-existing impairment of ventilator drive (sleep apnea or obesity hypoventilation syndrome), the use of other sedative agents, and conditions that interfere with diaphragmatic function such as thoracic surgery. Careful titration of opioids is important for all patients but especially for this high-risk group and for those with tenuous respiratory function.[68]

Opioid-induced hyperalgesia is defined as an increase in pain response related to opioid exposure after minimal or even no exposure to noxious stimuli.[69] The clinical impact of opioid-induced hyperalgesia ranges from an acute loss of pain relief to the development of chronic pain syndrome. The proposed mechanism for opioid-induced hyperalgesia, sensitization of pro-nociceptive pathways through activation of NMDA receptors resulting in an influx of intracellular calcium which in turn heightens the response to pain, provides the rationale for using NMDA receptor antagonists, such as ketamine and methadone. Other management approaches include multimodal analgesic strategies, careful opioid dose titration, opioid rotation, and the use of regional anesthetic techniques.

Given the opioid epidemic there is growing concern with the use of opioids in the ICU and the misuse potential after discharge. Approximately 20% to 40% of ICU patients are prescribed opioids at discharge, with only 3% continuing to persistent use; however, more research is needed to understand the impact of opioids in the ICU and chronic opioid use and misuse.[6,70]

Fentanyl

Fentanyl is a widely used opioid in United States ICUs because of its rapid onset of action and ease of titration. It is largely metabolized by CYP3A4 and may interact with commonly used ICU medications including, but not limited to, midazolam, the azole antifungals, macrolides, protease inhibitors, barbiturates, rifampin. Only 10% of fentanyl is excreted unchanged by the kidney, and no renally excreted active metabolites are formed.[8] Therefore, fentanyl dosing requirements are unchanged in patients with impaired kidney function though they may be reduced in patients with hepatic disease or heart failure.[71]

Fentanyl has 5-hydroxytryptamine 1A agonist properties and may occasionally be associated with serotonin syndrome in patients receiving other serotonergic medications.[72,73]

Hydromorphone

Hydromorphone is a potent semisynthetic opioid with a relatively long duration of action (~3 hours) which may be beneficial if prolonged pain relief is required, but this same feature interferes with dose titration.[8] It is hepatically cleared and is safe to use in patients with kidney disease though accumulation of the neurotoxic 3-glucuronide metabolite is possible in this setting. Important differences in opioid dosing equivalents should be appreciated when using hydromorphone since the IV formulation is approximately seven times more potent than IV morphine.

Morphine

Contemporary use of morphine is traditionally limited for the treatment of dyspnea, myocardial infarction (histamine releasing properties result in venodilation and a reduction in preload), and as a part of palliative care for the terminally ill. Use of this opioid is complicated by its relatively slow onset of action, potential for bronchospasm, and the accumulation of active metabolites. The 3 and 6 glucuronide salts are associated with neurotoxicity which may lead to seizures and oversedation respectively in patients with impaired kidney function.[8]

Methadone

Methadone is a unique synthetic opioid since it is a μ receptor agonist as well as an NMDA receptor antagonist. This latter pharmacologic property may restore analgesic responsiveness in chronic pain patients who have exhibited tolerance to high doses of standard opioids. This opioid has a complex pharmacokinetic profile with a half-life that varies from 15 to 60 hours depending on hepatic and CYPs 3A4 and 2B6 enzyme function and the presence of drug-drug interactions. Methadone can facilitate extubation and discontinuance of opioid infusions,[74,75] but is associated with a number of clinically important issues. There are no reliable dose equivalents when transitioning from standard opioids to methadone so conservative initial dosing and careful titration is necessary with rescue doses of another opioid in place until an adequate methadone regimen is determined.[76] When converting from IV to oral methadone the oral availability is greater than 75% and a 1:1.3 ratio should be used.[77] Another concern involves QTc prolongation and the potential for ventricular dysrhythmias such as torsades de pointes. Risk factors for torsades include the administration of more than 30 mg per day, concurrent use of other QTc prolonging medications, electrolyte imbalances, and the presence of structural or arrhythmogenic heart disease. Baseline and follow-up ECG monitoring is recommended for patients with these risk factors along with maintenance of serum potassium and magnesium in normal ranges.[78] And lastly, like fentanyl, methadone induces serotonin syndrome when used concurrently with other serotonergic medications.[79,80]

Remifentanil

Remifentanil is an ultra-short acting opioid administered as an infusion. Remifentanil is advantageous in patients with organ dysfunction and in those who require frequent neurologic evaluations since it is degraded by plasma esterases resulting in a 3 minute half-life. This short half-life can also pose a risk for patients if the infusion is inadvertently interrupted exposing patients to a loss of analgesia as well as the potential for acute opioid withdrawal. Healthcare professionals should be informed of these risks and be prepared to administer longer acting opioids if this occurs. Lastly, the risk of opioid induced hyperalgesia may be greater with remifentanil compared to other opioids.[81,82]

Buprenorphine

Buprenorphine is a partial μ-opioid receptor agonist with kappa opioid receptor antagonist properties. Buprenorphine's use in the ICU is usually reserved for continuation of pre-ICU admission treatment for opioid dependence or chronic pain. Because of its opioid antagonist properties, patients who have a history of recent buprenorphine administration will often require much higher doses of standard opioids for their ICU care.[83]

Tramadol

Tramadol is an oral synthetic opioid that modulates the pain response in a number of ways including weak μ opioid receptor activity, serotonin release, inhibition of norepinephrine reuptake and by acting as an NMDA antagonist. While tramadol may produce less respiratory depression than standard opioids, its use in the ICU is limited by its low potency, medication interactions (CYP metabolism), epileptogenic properties. and the potential to induce serotonin syndrome.[84]

Nonopioid Analgesic Agents

Adjunctive, nonopioid medications such as acetaminophen, ketamine, nonsteroidal anti-inflammatory drugs, and neuropathic agents such as pregabalin and gabapentin are used with the intention of sparing opioid use and attendant adverse medication reactions (ileus, respiratory depression) and improving pain management. These potential benefits must be weighed against their adverse medication reactions, for example, liver toxicity with acetaminophen, risk of bleeding with NSAIDs, neurotoxicity and behavioral issues with ketamine, and altered mental status with gabapentin.[85]

Acetaminophen

Acetaminophen, a central cyclooxygenase inhibitor, consistently decreases opioid dosing requirements by as much as 20% in non-ICU trials. Unfortunately, there are very few supportive ICU-specific studies. The PADIS guidelines suggest that acetaminophen should be considered for pain relief especially in patients at high risk for opioid-associated side effects (eg, patients recovering from abdominal surgery or at risk for ileus or nausea or vomiting).[7] It should be appreciated that the IV formulation of acetaminophen has been associated with hypotension with a reduction in mean arterial pressure of greater than 15 mm Hg in as many as 50% of patients. The reasons for this remain unclear.[86] Daily dosing of acetaminophen for acute short-term use should be limited to less than 4 gm in those with cirrhosis or a history of alcohol use disorder and for longer term use, a maximum of 2 to 3 gm daily is recommended.[85]

Gabapentinoids

Gabapentin and pregabalin modulate pain response by interfering with the influx of intracellular calcium which reduces glutamate and substance P release. Since gabapentinoids provide opioid sparing properties, the PADIS guidelines recommend the use of these medications for the treatment of pain.[7] No difference in time to extubation or ICU length of stay is apparent in patients receiving gabapentinoids versus those who do not.

Gabapentinoid medications have limitations, primarily involving their sedative potential and their lack of IV availability. Since they are renally eliminated, dosing needs to be adjusted in patients with impaired kidney function.

Ketamine

Ketamine is noncompetitive NMDA receptor antagonist blocking the effects of glutamate release. Its use is associated with dissociative, sedative, analgesic, and amnestic effects.[87] Other properties of ketamine include the release of endogenous catecholamines (helpful in patients with hypotension and hazardous in those with hypertension), bronchodilation (helpful in asthma exacerbations), and lack of interference with respiratory drive (helpful in patients with tenuous pulmonary function) and gastrointestinal motility (helpful in patients with ileus or constipation). Low dose ketamine infusions are adjunctive to opioid therapy in the post-surgical ICU setting due to a reduction in morphine consumption.[7,88] Adverse medication reactions of ketamine include neuropsychiatric effects (emergence phenomenon, confusion, nightmares, hallucinations), which are rarely seen on medication discontinuance with doses less than 0.5 mg/kg/hour, hypertension, diplopia, nystagmus, and nausea and vomiting. Relative contraindications for ketamine with subdissociative dosing are not well established, but a recent consensus guideline includes poorly controlled cardiovascular disease or hypertension, pregnancy, active psychosis, and severe liver disease.[89] Though popular, additional research to define ICU-specific risks, benefits, and dosing schemes with ketamine are needed.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs inhibit prostaglandin synthesis in response to noxious stimuli and interfere with the acute inflammatory response. In the setting of postoperative ICU pain, NSAIDs may decrease opioid requirements without effecting the frequency of nausea/vomiting and without increasing the risk for bleeding or kidney injury. None-the-less, because of their well-established adverse medication reactions, NSAIDs should be avoided in patients with bleeding diathesis and kidney disease.[7]

α2 Agonists

Dexmedetomidine and clonidine are central α2 receptor agonists commonly used in the ICU. They are typically regarded as sedative agents, but they have opioid sparing properties as well. Pain modulation is likely mediated by α2 receptor agonism in the substantia gelatinosa in the dorsal horn of the spinal column.[90] These agents are discussed in detail in the Pharmacologic Management of Agitation section of this chapter.

Agitation

Most ICU patients will require some form of pharmacologic strategy to maintain comfort and safety, but these same interventions may predispose to high morbidity. To maintain the fine balance between efficacy and harm, carefully choosing both an appropriate sedation option and titration goal is required. These choices can affect short- and long-term outcomes including the duration of mechanical ventilation, ICU length of stay, 90-day mortality, the incidence of delirium, and long-term neurocognitive and psychologic function.[91,92]

Benzodiazepines

⑧ Benzodiazepines activate γ- aminobutyric acid A (GABA) receptors and have anxiolytic, amnestic, sedative and anticonvulsant activity. These agents can cause respiratory depression, altered sensorium, and hypotension especially with concurrent opioid use. The benzodiazepines are no longer considered first line agents for the treatment of agitation in the ICU since they are associated with prolonged time on the ventilator and in the ICU and may increase the risk for delirium, especially when administered as continuous infusions[7,8,42,93] These outcome differences are likely related to challenges with dose titration arising from benzodiazepine pharmacodynamic and pharmacokinetic properties.

Midazolam is metabolized by CYP3A4 with a half-life of approximately 3 hours after IV bolus administration. This lipid soluble benzodiazepine is often used in the ICU since its onset is very quick and it can be given both as a bolus and infusion. With short-term use, the duration of action of midazolam is brief, but can be dramatically prolonged when administered as an infusion for longer than 48 hours.[8] The lipophilicity of midazolam helps to explain this effect, termed “context sensitive half-life” where the parent drug accumulates as a function of duration of exposure resulting in prolongation of its offset.[94] The extended activity of midazolam resulting from context sensitive half-life issues is compounded by the accumulation of an active metabolite (α1-hydroxymidazolam) in patients with kidney disease.[95]

Lorazepam, a longer acting benzodiazepine with relatively low lipid solubility and associated slower onset of effect, is used less frequently in the ICU. It is generally prescribed for the treatment of alcohol withdrawal and for acute treatment of seizures. Its utility as an infusion is limited by the large amount of the diluent, propylene glycol, present in the IV formulation that can accumulate in a dose dependent fashion to cause metabolic acidosis, renal tubular dysfunction, and hyperosmolarity.[96]

Despite these short-comings, the benzodiazepines remain important sedative options for select patients. They may be preferred as premedications for procedures, to provide deep sedation particularly when amnesia is required (such as when neuromuscular blockade is used), to acutely treat seizures, for the management of alcohol withdrawal, and perhaps in conjunction with opioid-based analgosedation to sedate patients who are hemodynamically compromised since propofol and dexmedetomidine are commonly associated with hypotension.[97,98]

Propofol

⑧ Both the 2013 PAD and 2018 PADIS guidelines suggest that either propofol or dexmedetomidine are preferred as sedative agents over the benzodiazepines in critically ill mechanically ventilated ICU patients.[7,8,99] Propofol binds to multiple central nervous system sites including GABA, glycine, nicotinic and muscarinic receptors to produce sedative, anxiolytic, amnestic, antiemetic and anticonvulsant activity. It is highly lipid soluble with rapid transport through the blood-brain barrier into and out of the brain. The resultant ease of titration makes propofol a desirable agent for many different types of patients and clinical conditions especially when frequent neurologic evaluations are required and to facilitate daily sedation interruption efforts. Its use is also associated with a shorter length of stay and a lower incidence of delirium compared to the benzodiazepines.[100] Propofol and dexmedetomidine have similar outcomes in regard to length of mechanical ventilation, delirium and mortality.[101] The choice between propofol and dexmedetomidine is determined by the need for mechanical ventilation (dexmedetomidine is fine for patients who are not ventilated) and the desired depth of sedation and amnestic effects (propofol use is favored for deep sedation and amnesia).

Propofol does not possess analgesic activity, is associated with hypotension, depresses respiratory drive, interferes with airway protection and is associated with a low frequency, but highly morbid condition called the propofol-related infusion syndrome (PRIS).[102] Risk factors have traditionally focused on exposure (dose exceeding 4mg/kg/hr and duration longer than 48 hours), but some patients may experience PRIS with lower doses and within a short period after infusion initiation. Mitochondrial dysfunction is thought to mediate this often deadly reaction which is characterized by hypotension, bradycardia, Brugada-like arrhythmias, creatine-kinase elevation, metabolic acidosis, and death.[103] Since there is no antidote for this syndrome, early recognition, discontinuance of propofol and supportive measures are required.

Propofol is administered as an infusion containing 10% lipid emulsion with egg lecithin and soybean oil and therefore it should be avoided in patients with allergies to eggs or soybeans. In addition, the caloric load of propofol infusions (1.1 kcal/mL [4.6 kJ/mL]) must be considered when nutritional requirements are calculated. The lipid carrier vehicle may increase the free fraction of other medications such as valproate.[104]

Dexmedetomidine

⑧ Dexmedetomidine is a selective central α-2 receptor agonist that inhibits synaptic release of norepinephrine in the coeruleus locum and dorsal region of the spinal cord, and other areas, and offers anxiolytic, sympatholytic and opioid sparing activity without significantly impairing respiratory drive.[90] It can be administered to patients who are not supported by mechanical ventilation and offers an option for multimodal analgesia. These attributes are especially useful in treating agitated patients who are in the process of weaning from mechanical ventilation, in nonintubated patients with tenuous respiratory function, and may be helpful in patients with delirium or withdrawing from alcohol or opioids.[105] Dexmedetomidine infusions offer a light sedative state allowing patients to be interactive, and may facilitate pain assessment, mobilization efforts, and accurate delirium screening. The cooperative sedation produced by dexmedetomidine precludes its use for patients requiring deep sedation or amnesia. In addition, dexmedetomidine should be used very cautiously in patients with hemodynamic instability or reduced left ventricular function since its central α-2 receptor agonist properties can result in bradycardia and hypotension.[100,105]

Alternative Sedative Agents

No new sedative agents for ICU use have been FDA approved since dexmedetomidine in 1999, and all existing options are limited by efficacy, which varies by patient characteristics, development of adverse medication reactions, and the need for IV administration in a monitored setting. In an effort to explore alternative approaches, older medications have been repurposed in novel ways to help treat agitation in patients not responding to or intolerant of traditional agents and to help transition patients to non-ICU settings. For example, clonidine may aid in alcohol or opioid withdrawal syndromes, be employed as a part of multimodal pain relief, and used as an enteral alternative to dexmedetomidine. Valproate may be considered for agitation in patients with a history of bipolar disease, traumatic brain injury, or with seizure disorders. Phenobarbital has found utility in the setting of alcohol or benzodiazepine withdrawal. All three of these alternative agents carry some risk; clonidine with its withdrawal syndrome and hemodynamic effects, valproate and its association with hyperammonemia and liver derangement, and phenobarbital with its drug interaction profile and potential for excessive sedation. As is true with all sedative agents, patient-specific features and goals should guide medication choice.[106]

Delirium

②⑦ The most important and perhaps the only strategy to effectively treat delirium is to identify and correct or reverse its underlying cause, which may include infections, metabolic derangements, hypoxia, hyperthermia, pain, acidosis, central nervous system diseases, medication/substance use or withdrawal. Traditional pharmacologic treatment options for the symptoms of agitated delirium include haloperidol and the atypical antipsychotics. These agents block dopamine, serotonin, histamine, α adrenergic, and muscarinic receptors resulting in mood stabilizing effects. They do not affect respiratory drive, but may variably prolong the QTc depending on the agent used. In addition, long-term administration has been associated with cardiovascular events and death especially in older patients with dementia.[107] These agents may not influence the severity or duration of delirium, and may not have a beneficial effect on clinically relevant outcomes such as time on the ventilator, time in the ICU, and mortality.[62] The PADIS guidelines do not recommend routine use of antipsychotic agents for patients with delirium.[7] Whether these medications offer any benefit for the distress associated with delirium such as anxiety, fear, delusional thinking or hallucinations has yet to be determined. It is important to emphasize that as many as 75% of patients initiated on antipsychotic medications in the ICU are discharged from the ICU on these medications, and as many as 55% of patients are discharged from the hospital with prescriptions for these agents either intentionally or inadvertently resulting in exposure to potential adverse medication reaction risks including cardiovascular events and death.[108–110]

Currently, there is limited evidence to support the use of dexmedetomidine for intubated patients when agitated delirium interferes with extubation.[111] Dexmedetomidine may reduce delirium occurrence, but it is not clear if dexmedetomidine is useful for delirium that is not associated with agitation and for delirious patients where agitation does not preclude extubation efforts.[112]

Medication Withdrawal

Sedative and opioid withdrawal symptoms may be seen in as many as 30% of mechanically ventilated patients.[113,114] Unfortunately, the risks for developing withdrawal and its management are not clear. Withdrawal symptoms appears to be more frequent with the use of high doses for prolonged durations. Symptoms of withdrawal classically include the opposite of the medication's pharmacologic effect, but in general these symptoms can be regarded as nonspecific. The presence of unexplained agitation, tachycardia, hypertension, insomnia, delirium, nausea, diarrhea, diaphoresis and fever should prompt consideration of withdrawal. The 2013 PAD guidelines suggest that medications should be tapered over several days (if possible) when iatrogenic withdrawal is suspected.[8] Alternatively, the use of longer acting agents such as methadone or clonazepam can facilitate gradual discontinuance within a class of these medications. There is much to learn regarding iatrogenic withdrawal in ICU patients.

Transitions of Care Issues

⑤ As many as 75% of patients have medications initiated in the ICU to manage PAD and their continued need should be assessed with each transition of care, from ICU to floor and again at hospital discharge. The issue is confounded by the fact that nearly 40% of medications used in the ICU are "off-label" resulting in unclear indications for use.[115] Inadvertent or inappropriate continuation of ICU initiated psychoactive medications (antipsychotic agents, valproate, and clonidine) is well documented and occurs with a frequency of up to 75% after ICU discharge and 55% after hospital discharge[109,110,116–118] Some patients will require longer-term medical management with continuation of medications after ICU discharge, but for most, this represents improper prescribing. A number of strategies including electronic handoffs and process improvement efforts have limited efficacy, especially when considering prescriptions provided at hospital discharge.[119] Recommended strategies to prevent these occurrences include mandating inclusion of the indication for use along with a stop date or weaning plan within the medication order, initiating an electronic medical record-based alert system to warn prescribers that an ICU initiated medication is being continued after ICU discharge, and consistently offering medication reconciliation at every step (including transfer out of the ICU and discharge) within transitions of care.[109]

EVALUATION OF THERAPEUTIC OUTCOMES

⑤ Frequent systematic evaluations of PAD using validated assessment tools per the SCCM guidelines (at least four times per shift for pain and sedation/agitation and at least twice daily for delirium) aids in the timely recognition of these issues.[8] Positive assessments for PAD should prompt a search for inciting factors, initiate corrective action, and encourage preemptive or preventative interventions.

Persistent distressful or dangerous symptoms of PAD often require nonpharmacologic and/or pharmacologic management. These interventions should be evaluated for therapeutic efficacy and for possible adverse medication reactions. A multimodal approach which includes nonpharmacologic and pharmacologic strategies should be in place, and for most patients, goals of therapy include the provision of comfort and safety while allowing participation in their own care.[120,121] Sedation-induced coma should be reserved for specific indications since it adversely affects outcomes.

Medication withdrawal symptoms and resurgence of clinical issues upon discontinuance of medical management of PAD should be monitored, and if indicated, reinitiation of the medication or a dose tapering strategy should be considered. Continual reevaluation of the need for psychoactive or analgesic medications initiated in the ICU is required since many patients inadvertently or inappropriately remain on these agents even after hospital discharge.

CONCLUSION

Many important short and long-term outcomes in critical care patients are influenced by the management of PAD. Features that are common for the optimal management for PAD include the provision of preventative measures, the systematic assessment PAD, the establishment of appropriate therapeutic goals, the use of nonpharmacologic modalities, and only when these are inadequate, that pharmacologic options be employed. Since PAD in ICU patients is multifactorial, a multimodal interprofessional strategy is generally beneficial. Lastly, pharmacological management choices are driven by patient context, therapeutic goals, and a thorough evaluation of risks and burdens by considering medication pharmacodynamics, pharmacokinetics, and adverse medication reaction profiles.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old male was involved in a motor vehicle crash and suffered significant chest trauma including multiple rib fractures. He has developed respiratory failure with evidence of pneumonia and a pleural effusion and now requires mechanical ventilation and the placement of a chest tube. Which assessment tool should be utilized to monitor the patient's pain?

   A. Richmond Agitation Sedation Scale (RASS)

   B. Confusion Assessment method for the ICU (CAM-ICU)

   C. Intensive Care Delirium Screening Checklist (ICDSC)

   D. Critical Care Pain Observation Tool (CPOT)

2. An acute respiratory distress syndrome patient is being paralyzed with cisatracurium and deeply sedated with fentanyl and propofol to facilitate mechanical ventilation with a lung protective strategy. The patient's nurse is interested in discontinuing fentanyl drip because the documented CPOT score = 0. The RASS score is −5. Which of the following is the *best* therapeutic option at this time?

   A. Turn off the fentanyl infusion since there is no evidence for pain

   B. Have the nurse monitor vital signs after turning off the fentanyl infusion since these are valid indicators of pain

   C. Retain fentanyl since pain cannot be assessed with CPOT in patients without motor activity

   D. Ask a surrogate to assess the patient's pain before turning off the fentanyl

3. Which of the following is the *most likely* to influence ICU delirium and pain assessments?

   A. Sedation during delirium and pain assessments

   B. Lack of a validated ICU delirium and pain assessment tools

   C. The subjectivity of validated delirium and pain assessment tools

   D. Caregiver inexperience in administering these assessments

4. A non-intubated patient with respiratory distress in the setting of an acute exacerbation of chronic obstructive pulmonary disease develops agitation that seems related to his dyspnea. Aerosolized bronchodilators help his oxygenation, but even after a 2 mg dose of IV midazolam, he remains agitated. His mean arterial blood pressure is 60 mm Hg without vasopressor support. When asked about any discomfort, he rates his pain as 4 on the numeric rating scale. Which of the following is the *best* initial therapeutic option for this patient?

   A. Propofol infusion after intubation

   B. Dexmedetomidine infusion without intubation

   C. Intermittent fentanyl injection without intubation

   D. Midazolam infusion after intubation

5. Which statement is *true* regarding non-pharmacologic strategies for PAD management?

   A. They are most effective when used in a multifaceted approach

   B. They are made more efficient by focusing on one effort

   C. They are generally ineffective, but not likely to cause harm

   D. They do not lend themselves to a bundled approach

6. An 86-year-old woman with a minimal medical history presents with a urinary tract infection and acutely becomes sleepy, withdrawn, and confused. She is unable to follow commands appropriately though she has no history of cognitive dysfunction. Diagnostic screening tests have not yet been performed. Which condition is the *most likely* explanation for her behavior?

   A. Hypoactive or decreased arousal delirium

   B. Post-traumatic stress disorder (PTSD)

   C. Dementia

   D. Depression with dementia

7. An older adult patient (NKDA, no significant past medical history) is determined to have delirium based on a screening assessment tool, the CAM-ICU. The urine grows *E. Coli* susceptible to most antibiotics. What is the *best* treatment for this patient's psychiatric symptoms at this time?

   A. Intravenous haloperidol

   B. Enteral quetiapine

   C. Appropriate antibiotics

   D. Intramuscular olanzapine

8. Most opioid medications confer pain relief by μ-opioid receptor agonist properties. Which of the following may have utility in patients who have experienced tolerance to opioid-induced analgesia?

   A. Morphine because its active metabolites act synergistically with the parent drug

   B. Methadone because of its NMDA receptor agonist properties

   C. Hydromorphone because it is a synthetic opioid and more potent than morphine

   D. Remifentanil because it is easily titratable

9. When compared to infusions of propofol and dexmedetomidine, midazolam infusions are associated with which of the following?

   A. A longer duration of mechanical ventilation and higher mortality

   B. A longer duration of mechanical ventilation and ICU length of stay

   C. An increased risk for delirium without affecting time on the ventilator and in the ICU

   D. A reduction in ICU costs since its acquisition costs are less than the other two options

10. As a part of a quality assurance program, you find that 25% of patients continue to receive ICU initiated psychoactive medications when they are transferred to a non-ICU nursing unit. Which strategy is *most appropriate* to employ to reduce inappropriate or unintended medication continuation?

    A. Create a policy mandating discontinuance of all psychoactive medications prior to transfer out of the ICU

    B. Allow the practice to continue since the risk of recurrence of adverse or dangerous behaviors is so high

    C. Allow these medications to be continued in a non-ICU setting, but with proactive orders to taper dosing to ensure that they are completely discontinued within 5 days

    D. Ensure that medication reconciliation is in place during all transitions of care to determine if the initial indications remain for psychoactive medication use

11. Ventilatory support of patients with acute respiratory distress syndrome is often prolonged and requires sustained sedation and analgesia for comfort and to facilitate synchrony with the ventilator. Many of these patients also have concomitant kidney injury. Which of the following combinations is *preferred* in this setting?

    A. Fentanyl and midazolam

    B. Fentanyl and propofol

    C. Morphine and propofol

    D. Hydromorphone and midazolam

12. An 80-year-old male who resides in a skilled nursing facility is admitted with septic shock and respiratory failure related to pneumonia. His mean arterial blood pressure is 60 mm Hg and vasopressor therapy is initiated. His urine output is diminished and his serum creatinine has doubled over baseline in the last 24 hours. After intubation, he becomes very agitated and requires pharmacologic management for safety and comfort. Which of the following options is the *best* choice for managing his agitation?

    A. Fentanyl and propofol infusions

    B. Fentanyl infusion and intermittent midazolam

    C. Dexmedetomidine infusion

    D. Morphine infusion and intermittent intravenous haloperidol

13. A 75-year-old male is admitted to the ICU with respiratory distress due to COPD exacerbation. He has a history of atrial fibrillation treated with diltiazem 30 mg every 6 hours for rate control and chronic back pain treated with acetaminophen on an as needed basis. Within 12 hours, he becomes agitated and is provided a dexmedetomidine infusion, but his heart rate is now 45 beats per minute. He is not requiring mechanical ventilation, and the team is interested in an alternative regimen that will provide comfort while preserving his respiratory drive. Which of the following strategies would be *preferred*?

    A. Fentanyl infusion titrated to pain relief

B. Scheduled enteral clonidine with as needed morphine

C. Scheduled enteral quetiapine with as needed fentanyl

D. Scheduled enteral acetaminophen with as needed hydromorphone injection

14. A 35-year-old female suffers extensive thoracic trauma after a motor vehicle crash. Surgical intervention was successful, but she now has an ileus likely due to post-operative use of continuous infusion fentanyl and this interferes with achieving her nutritional goals. Which of the following is *not* a good option for relief of moderate to severe pain in this patient?

A. Add ketamine infusion with scheduled acetaminophen

B. Continue fentanyl infusion with aggressive scheduled bowel preparations and add acetaminophen

C. Transition to methadone for pain relief

D. Substitute dexmedetomidine for fentanyl and add scheduled acetaminophen

15. Which psychoactive medication is *not* associated with withdrawal symptoms with abrupt discontinuance after prolonged high dose exposure?

A. Quetiapine

B. Clonidine

C. Midazolam

D. Fentanyl

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** The RASS is used to monitor sedation, and CAM-ICU and ICDSC are used to monitor delirium. CPOT is an option to monitor pain in critically ill patients unable to communicate their pain.

2. **C.** We assume that pain/discomfort is present even in patients at rest and perhaps in particular in patients who are immobile and receiving nonphysiologic respirations. There is no reliable way to assess pain in a patient who is deeply sedated and pharmacologically paralyzed since CPOT requires some motor activity for assessment. Surrogate pain evaluations do not offer any value in unresponsive, paralyzed patients and vital signs are not adequate indicators of pain in the ICU.

3. **A.** ICU delirium and pain assessment tools have been evaluated for reliability, feasibility, validity, and clinical utility in clinical environments, and as such, make selections B, C and D incorrect. Data on the influence of sedation levels or arousal to evaluate pain is limited to one study (Reference 40), while the influence of arousal levels on delirium assessments is well supported with data from over 12,000 patient-specific evaluations. When patients are not able to track with their eyes for 10 seconds after verbal stimuli, the frequency of positive delirium assessments is 75%, but decreases to 22% when they are wakeful (Reference 5).

4. **C.** Pain may be present in a resting patient should always be assessed as a reason for agitation. A numeric rating score of 4 suggests that pain is present in this patient and should be addressed. Propofol would likely control his agitation by masking pain, but would require the insertion of an endotracheal tube and initiation of mechanical ventilator support. It is also associated with many adverse medication reactions such as hemodynamic instability. Dexmedetomidine might be a reasonable choice since it offers opioid sparing properties and does not require mechanical ventilation for use, but it is also associated with hemodynamic instability. Midazolam infusions should be reserved for specific patient populations since they are associated with prolonged time on the ventilator and in the ICU and are also associated with delirium.

5. **A.** The etiology of PAD is often multifactorial and it should be managed using a multifaceted approach; ideally without resorting to pharmacologic strategies. While data supporting efficacy of these nonpharmacologic interventions are sparse, they may be helpful and are not likely to cause harm. Music is a good example of a potentially effective means of influencing analgesic requirements which carries little risk for harm (as long as patient

listening preference is considered). Utilizing these strategies as a part of a bundled approach to ICU care can have a positive impact on outcomes.

6. **A.** Delirium is characterized by acute changes in mental status and arousal associated with inattention that is initiated by a medical issue such as an infection. PTSD is a more chronic condition and usually is apparent weeks after a traumatic event. Dementia can be distinguished from delirium by the chronicity of symptoms. Depression may help to explain her lethargy, but should not cause confusion, and it is generally not a condition that occurs acutely without an inciting factor.

7. **C.** Treatment of delirium should be directed at its cause, and in this case, it is likely the infection. There are no data to support the use of antipsychotics in delirium of any kind, but especially when behaviors are not dangerous to self or to others.

8. **B.** All of the answers contain accurate descriptions of the various opioid options, but opioid choice is best determined by patient context. Morphine has active metabolites, but one of them actually heightens the perception of pain. Hydromorphone is indeed synthetic and the IV formulation is approximately seven times more potent than IV morphine. But opioid tolerance isn't an issue of dosing as much as it is activation of the NMDA receptor site resulting in heightened pain perception. Remifentanil has a half-life of 3 minutes, is administered as an IV infusion, and is associated with rapid onset of opioid hyperalgesia. It would not be a good choice for these reasons. Methadone has NMDA receptor agonist properties and has found utility in restoring analgesia for patients who have become tolerant to standard opioids.

9. **B.** Randomized controlled trials have demonstrated that midazolam use is not associated with an increase in mortality, but it does adversely influence time on the ventilator and in the ICU. In addition, infusions of midazolam are associated with an increased risk for delirium. Acquisition costs for midazolam are lower than for dexmedetomidine and propofol, but these savings are negated when the costs of care (increased time in the ICU and on the ventilator) are considered.

10. **D.** The continued need for all medications, but particularly those initiated in the ICU for an acute indication should be evaluated during all transitions of care. The decision about whether to continue, discontinue, or taper dosing of these medications should consider patient context. This makes protocolization using automatic stop or tapering orders ill-advised from a patient care perspective.

11. **B.** Both of these agents are short acting, are not cleared by the kidneys and do not produce active metabolites. The midazolam component in answers A and D degrades to an active metabolite that has two-thirds the activity of the parent drug and it accumulates in kidney disease. Answer C is incorrect since morphine degrades to two active metabolites that accumulate in kidney disease. Hydromorphone is generally regarded as an appropriate opioid in renal disease, but it carries the small risk of accumulation of a neurotoxic metabolite.

12. **B.** Agitated hemodynamically compromised patients are challenging to manage since many of the sedatives we offer (propofol and dexmedetomidine) can cause or exacerbate hypotension. Morphine is not a good choice since it can cause venodilation related to histamine release and also since its active metabolites will accumulate in kidney disease. Fentanyl does not cause histamine release and has no active metabolites. When analgosedation is offered, additional standard sedation is required in approximately 50% of patients. For breakthrough agitation, intermittent midazolam is often effective and with this mode of administration (vs a continuous infusion), the risk for delirium is low.

13. **D.** His history includes the successful use of acetaminophen, but there may be new onset pain that could be effectively and safely treated with as needed intermittent IV hydromorphone. Infusions of opioids should be avoided due their potential respiratory depression activity. Clonidine is pharmacologically related to dexmedetomidine and can be expected to share in its adverse medication reaction profile including bradycardia. There are no data supporting the benefits of quetiapine in agitated patients.

14. **C.** Multimodal analgesia can result in opioid sparing properties making combinations of ketamine and dexmedetomidine appropriate choices. If an opioid is needed, the provision of bowel preparations should be in place. The use of methadone as a single pain agent would not likely offer an advantage over continuous infusion fentanyl in terms of her gastrointestinal function.

15. **A.** There is no pharmacologic withdrawal that is associated with the antipsychotics, but resurgence of psychiatric symptoms may occur and probably warrant cautious discontinuance or downward dose titration. Withdrawal symptoms from opioids and benzodiazepines can be expected after prolonged exposure. Seizures associated with benzodiazepine withdrawal is potentially life threatening. Clonidine withdrawal syndrome also included potentially life-threatening symptoms including hypertension and tachycardia.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter e28: Palliative and End-of-Life Care

Mary Lynn McPherson; Jessica E. Geiger

KEY CONCEPTS

KEY CONCEPTS

① Palliative care may be provided to any patient with a serious illness, at any point in the course of the illness, including while a patient receives curative or disease-focused therapy.

② Hospice is a form of palliative care, which has been defined by Medicare to encompass care solely focused on comfort and quality of life for patients with a likely prognosis of 6 months or less.

③ Pain is a common symptom among patients receiving palliative care and may be managed safely and effectively using nonopioid, adjuvant, and/or opioid therapies.

④ Opioids are the drug of choice for the management of dyspnea.

⑤ Constipation, nausea, vomiting, anxiety, and delirium are common symptoms among patients receiving palliative care and may be managed effectively with drug and nondrug therapies.

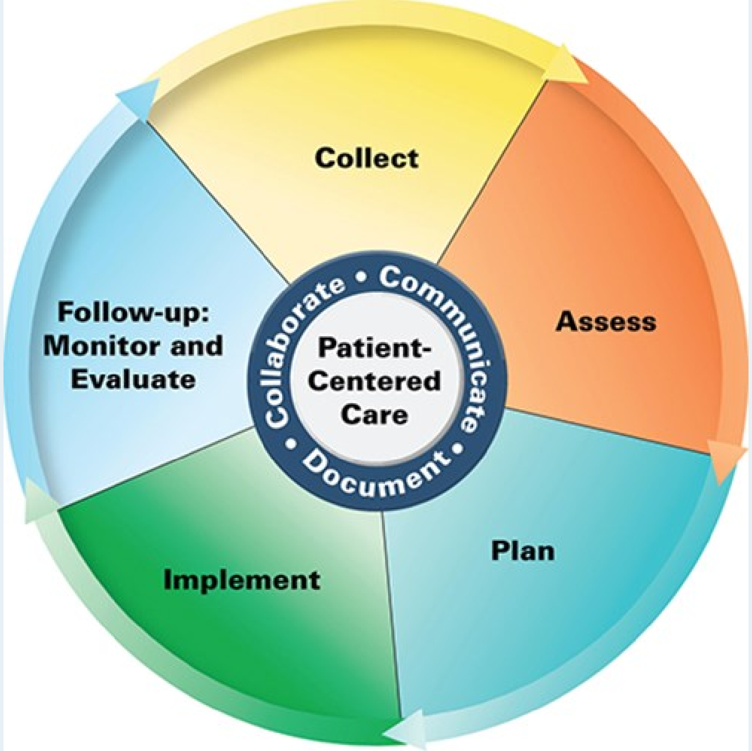
⑥ End-of-life care can be provided to patients in the last days of their lives through palliative or hospice care and provides the management of common terminal symptoms.

⑦ Identifying a patient’s goals and structuring care to achieve these goals is a key component of palliative care. Identifying a patient’s goals of care involves communication with patients, their families and/or caregivers, as well as other healthcare professionals.

⑧ Addressing nonphysical needs—including spiritual, faith, and psychosocial—is a key component of providing quality palliative care.

PATIENT CARE PROCESS

Patient Care Process for Cancer Pain



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient-specific information (age, sex, goal of care, patient and family beliefs/preferences regarding pain management)
- Past medical history, concurrent disease states
- Social history (alcohol or other substance use)
- Current medications
- Subjective data
  - Pain score/severity (eg, at best, at worst, at rest, with movement)
  - Time course (acute vs chronic and intermittent vs persistent) of pain
  - Patient description of pain quality (eg, achy, sharp, localized, diffuse)
  - Associated symptoms
  - Precipitating or palliating factors
  - Impact on patient’s ability to function
- Objective data
  - Respiratory rate
  - Labs: serum creatinine (SCr), estimated glomerular filtration rate (eGFR), liver function tests (ALT, AST)
  - Electrocardiogram (ECG), QTc interval

Assess

- Etiology of pain
- Type of pain
  - Nociceptive, neuropathic, inflammatory, mixed
- Why are symptoms presenting now?
- Severity of symptoms
- Is pain stable/unstable?
- State prescription drug monitoring program data

Plan*

- Pain management regimen including drug and nondrug therapy, consider scheduled versus “as needed” or PRN therapy
  - Consider both adjuvant and/or opioid medications
- Monitoring parameters for efficacy (pain severity and patient functioning) and safety (adverse effects such as sedation, constipation, nausea, and other drug-specific adverse effects)
- Frequency of monitoring and follow-up
- Patient and caregiver education (eg, expectations improvement in pain severity and function, medication use, and expected adverse effects and management)
- Appropriate use of “as needed” or PRN medications
- Safe medication storage and disposal
- Referrals to other providers, if appropriate (eg, physical therapy, behavioral health, chaplain)

Implement*

- Provide education to patient, caregivers, and family members regarding treatment plan using the teach-back method
- Schedule follow-up labs and appointments as applicable

Follow-Up: Monitor and Evaluate

- Improvement in pain symptoms (severity, patient function)
- Presence of adverse effects (eg, sedation, constipation, nausea)
- Changes in renal/hepatic function
- Medication adherence

**Collaborate with patient, caregivers, and other healthcare professionals.*

Scroll down to Episode 15: "Ten Tips Palliative Care Pharmacists Want the Palliative Care Team to Know When Caring for Patients." Select any two tips discussed in the podcast and critically think through why the tip is an important one for the rest of the hospice or palliative care team. This podcast is useful to enhance your understanding regarding the PLAN and MONITORING and FOLLOW-UP steps in the patient care process.

INTRODUCTION

① Palliative care, or palliative medicine, is specialized care provided to patients with serious illness with a goal of managing symptoms and helping patients to cope with their illnesses.[1] It is provided by an interdisciplinary team of healthcare professionals, including physicians, pharmacists, nurses, nurse practitioners, social workers, chaplains, and others.[2] Palliative care is appropriate for any patient with a serious or potentially life-limiting illness, at any point during the time course of that illness. Common diseases for which palliative care is appropriate include cancer, heart failure, advanced lung disease such as chronic obstructive pulmonary disease (COPD), organ failure such as liver or renal failure, and neurologic diseases such as dementia and Parkinson disease.[2] Patients may receive palliative care throughout the course of a serious illness, including while the patient receives treatment aimed at managing or curing the disease. If or when the serious illness progresses and disease-focused therapies are no longer helpful or desired, palliative care continues to be provided to manage symptoms and maximize quality of life.

Provision of palliative and end-of-life care to patients with limited prognoses has been shown to improve patient and caregiver satisfaction,[3–5] reduce healthcare utilization,[3,4] and decrease healthcare costs.[3,4,6] In addition to providing symptom management, improving patient and caregiver satisfaction, and reducing healthcare costs, early integration of palliative care has been shown to increase survival among patients with advanced cancer.[7,8]

Because of the evidence supporting the benefits of palliative care, clinical practice guidelines for serious illnesses incorporate palliative care into treatment recommendations. Both the American Society of Clinical Oncology and National Comprehensive Cancer Network recommend palliative care as a component of oncology management.[9,10] In addition, the American College of Cardiology Foundation/American Heart Association practice guideline for the management of heart failure supports the incorporation of palliative care into the management of patients with advanced heart failure due to its effectiveness in increasing quality of life.[11]

WHAT IS HOSPICE?

② In the United States, hospice care is a Medicare-defined insurance benefit and is a form of palliative care that is focused on caring for patients with a life expectancy of 6 months or less.[12] Hospice care is generally provided when a patient is no longer pursuing disease-focused therapies and the decision has been made to focus solely on comfort and quality of life.[12,13] Although commonly associated with end-stage cancer, the frequency of noncancer diagnoses among hospice patients more than doubled between 1998 and 2008.[14] In 2014, the most recent year for which data are available, the most common hospice diagnoses were as follows: noncancer diagnoses (63.4% of hospice admissions) such as dementia (14.8%), heart disease (14.7%), and lung disease (9.3%). Cancer diagnoses accounted for 36.6% of hospice admissions.[14]

SYMPTOM MANAGEMENT IN PALLIATIVE CARE

Based on the diseases frequently encountered in hospice and palliative care, the most common symptoms managed by palliative care practitioners include pain, dyspnea, constipation, nausea and vomiting, anxiety, and delirium. The management of these symptoms is discussed below.

Pain

③ Pain is a common symptom among patients receiving palliative care, and providing effective pain management is a high priority of palliative care practitioners. A systematic review found that among studies of patients with cancer (any stage), 53% of patients experienced pain.[15] Among studies of patients with advanced cancer, 64% of patients experienced pain and more than 30% of patients who experienced cancer-related pain rated it as moderate or severe.[15] In an observational study of adults in the last 2 years of life with a variety of terminal diagnoses (eg, cardiac disease, cancer), the prevalence of moderate or severe pain was 26%, which increased to 46% during the last month of life.[16]

Developing an effective plan for pain management first requires pain assessment. The components of a pain assessment are timing, severity, patient description, location, palliative factors, precipitating factors, whether or not it radiates, and impact on patient function.

Ascertaining the time course of a patient's pain can help to distinguish acute from chronic pain. In addition, assessing the severity of pain at its best and worst throughout the day, as well as with movement and at rest, can provide helpful information in determining a treatment plan.[17] Patient descriptions of pain, such as its quality, precipitating or palliating factors, region affected, radiation of the pain (if any), temporal factors associated with the pain (ie, worse at night), and impact on the patient's ability to function can be extremely helpful in identifying the cause of pain and appropriate treatment. In noncommunicative patients, palliative care practitioners should assess patients for nonverbal indicators of pain such as grimacing, agitation, restlessness, or resistance to personal care.[17,18] Family members or caregivers can also provide useful information when assessing pain, as can validated tools such as the Pain Assessment in Advanced Dementia (PAINAD), Checklist of Nonverbal Pain Indicators (CNPI), and the Mahoney Pain Scale.[17,18] When assessing a patient's complaint of pain, a key distinction is between nociceptive pain and neuropathic pain, as drug therapy selection requires an understanding of pain pathophysiology.

Nociceptive pain is commonly described by patients as achy, throbbing, and dull.[17] Traditionally, nonopioid analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are often considered first line for pain management. However, among the palliative care patient population, the severity of pain or contraindications to nonopioid agents often necessitate the use of opioid agents such as morphine, oxycodone, or hydromorphone.[17] For example, acetaminophen is contraindicated in patients with severe hepatic impairment, while NSAIDs can increase the risk of cardiovascular events and gastrointestinal bleeding and should not be used in patients with renal impairment.[17] In patients without contraindications, NSAIDs are helpful for mild-to-moderate nociceptive pain, especially pain due to inflammatory processes such as pain from bony metastases in advanced cancer.[18] Opioids are frequently required for the management of moderate-to-severe pain in palliative care.[18] Although the World Health Organization ladder recommends weak opioid agonists such as tramadol and codeine as an intermediate step between nonopioid analgesics and strong opioids such as morphine and oxycodone, current evidence supports using lower initial doses of strong opioids in place of weak opioids to achieve better results in the management of cancer pain.[19,20] Opioid agents do not have a maximum ceiling dose and should instead be titrated to achieve acceptable pain relief while minimizing unacceptable adverse effects such as sedation and respiratory depression. After initiating opioid therapy, patients should be re-evaluated and doses titrated as required. For patients continuing to experience moderate pain, a dose increase of 25% to 50% is appropriate, while a dose increase of 50% to 100% is reasonable for patients experiencing severe pain.[17]

Patients often describe neuropathic pain as tingling, sharp, burning, electric shock-like, or numbness. Neuropathic pain is caused by damage to the central or peripheral nervous system itself, rather than actual or potential tissue damage, which is a characteristic of nociceptive pain.[21] The distinct pathophysiology underlying neuropathic pain necessitates a different approach to treatment, where adjuvant agents (drugs not originally developed for use as analgesics) are considered first line for pharmacologic management. Evidence-based recommendations for drug treatment of neuropathic pain identify tricyclic antidepressants (TCAs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and calcium channel alpha-2-delta ligands (gabapentin and pregabalin) as first-line therapies.[17,22] Traditional analgesics, such as opioids, are recommended as second-line (tramadol) or third-line therapy (morphine, oxycodone).[22]

When designing an analgesic regimen, the palliative care practitioner should first conduct a thorough assessment of the patient's pain to identify the pathophysiology whenever possible. For patients with persistent nociceptive pain, particularly that which is not expected to resolve (eg, pain due to advancing metastatic cancer without targeted interventions such as radiation), scheduling around-the-clock analgesics, rather than as-needed analgesics only is preferable. For patients receiving opioid therapy who require dosing throughout the day to maintain pain control, palliative care practitioners should consider initiation of a long-acting (LA) or extended-release (ER) formulation of an opioid.[17] Short-acting opioids should continue to be available for the management of "breakthrough" pain, which the patient may experience despite the LA or ER opioid.[17] When designing an opioid regimen consisting of LA and short-acting opioids, the basal, or LA, opioid is typically started at a dose representing 50% to 75% of a patient's total 24-hour opioid requirement, while the breakthrough, or short-acting, opioid is started at a dose representing 10% to 20% of the 24-hour opioid requirement.[17,23] If a patient's description or reason for pain is consistent with a neuropathic pathophysiology, adjuvant agents should be considered, and these agents should always be dosed around-the-clock.

When using opioid therapy as part of an analgesic regimen, palliative care practitioners must diligently monitor for and manage opioid adverse effects. Adverse effects frequently associated with opioid therapy include constipation, sedation, and confusion.[18] Adverse effects such as nausea, pruritus, urinary retention, and myoclonus may also occur with opioid therapy, although they are less common.[18] Respiratory depression, the most severe and worrisome opioid adverse effect, is always preceded by sedation and thus can typically be caught early with careful monitoring and slow dose titration. While tolerance occurs to most opioid adverse effects after the initial days of therapy or after an increase in dose, tolerance to opioid-induced constipation never develops.[24] Therefore, all patients receiving opioid therapy must be simultaneously initiated on a bowel regimen containing a stimulant laxative.[18,19] Although opioid adverse effects are typically similar for all agents within the class, individual patients may respond more or less favorably to a particular drug. If patients experience unacceptable adverse effects with one opioid agent, rotation to another agent within the class may provide analgesia while minimizing adverse effects.[19,24]

Dyspnea

④ Dyspnea, or the subjective sensation of breathlessness, is a common symptom in the palliative care patient population.[25] Although common among patients with advanced cancer, particularly those with lung tumors, dyspnea also occurs in patients with advanced cardiac and pulmonary disease such as heart failure and COPD.[26] Whenever possible, treating and reversing the underlying cause of dyspnea is preferred.[26] However, in patients with end-stage disease, reversing the underlying cause may no longer be possible, in which case symptoms should be controlled through pharmacologic and nonpharmacologic treatment.[25,26]

Opioids are first-line agents for the pharmacologic management of refractory dyspnea.[25,26] When used for the management of dyspnea, opioids are equally effective given through either the enteral or parenteral route. However, less evidence supports their use through the nebulized route of administration.[25,26] The beneficial effect of opioids on dyspnea is postulated to occur through multiple mechanisms: a vasodilatory effect on the pulmonary vasculature, a decrease in oxygen consumption during rest and exertion, and changes in the effects of carbon dioxide, oxygenation, and inspiratory flow resistive loading on ventilation.[25]

Benzodiazepines have been studied for the management of dyspnea. A 2011 Cochrane review found no evidence of benefit for benzodiazepines in the management of dyspnea.[27] Benzodiazepines are considered second- or third-line agents and are likely most useful in combination with opioid therapy in patients experiencing both dyspnea and related anxiety.[25,27]

Nonpharmacologic treatment strategies for dyspnea include use of a fan to create air movement across a patient's face, repositioning, pulmonary rehabilitation, and complementary therapies such as relaxation strategies. Although commonly requested by patients due to the symptoms of breathless, supplemental oxygen has not been beneficial for patients without hypoxia (PaO_2 <55 mm Hg [7.3 kPa]).[25]

Constipation

⑤ Constipation is a common symptom among patients receiving palliative care, due to both disease processes themselves (eg, tumor obstruction due to gastrointestinal cancers, electrolyte abnormalities, and impaired venous flow due heart failure) and the drugs used to manage other symptoms (eg, opioids, TCAs, antiemetics, and anticholinergics).[28] Estimates of the incidence of constipation vary widely, from 18% to 90% of patients, due to varying definitions of constipation.[28] Constipation generally includes the following symptoms: bowel movements that are difficult, painful, and/or infrequent; hard stools; and a sense of incomplete bowel evacuation.[28] The Rome III Criteria define functional constipation as "a functional bowel disorder that presents as persistently difficult, infrequent, or seemingly incomplete defecation, which do not meet [irritable bowel syndrome (IBS)] criteria."[29]

Constipation can be managed through nonpharmacological therapies such as increased intake of fluid and fiber, and increased physical activity. However, among the palliative care patient population, pharmacologic therapy with laxatives is generally required. Bulk-forming laxatives such as psyllium are generally not preferred for palliative care patients due to the risk of bowel obstruction or fecal impaction with inadequate fluid intake.[28] In a review of randomized controlled trials evaluating laxatives in patients receiving palliative care, no differences in efficacy were found among lactulose, senna, magnesium hydroxide plus liquid paraffin, and docusate plus senna.[28] All patients receiving opioids for the management of pain or dyspnea should receive prophylactic stimulant laxatives to prevent opioid-induced constipation.[18,19]

When designing a therapeutic regimen for a palliative care patient experiencing constipation, it is reasonable to consider agent availability, patient preference, and onset of action, as the evidence does not support increased efficacy of one agent over another. Combination laxative therapy with agents having different mechanisms of action is likely more effective than restricting therapy to a single laxative.[19] Peripheral opioid antagonists such as methylnaltrexone, naloxegol, and alvimopan should be reserved for opioid-induced constipation that does not respond to traditional laxative therapy.[19]

Nausea and Vomiting

Although less common than pain and dyspnea, nausea and vomiting are distressing symptoms frequently encountered in the palliative care patient population.[30] When evaluating a patient's complaint of nausea and/or vomiting, the palliative care practitioner should attempt to identify the cause of nausea and/or vomiting to identify potentially reversible causes such as those due to hyperglycemia, electrolyte abnormalities, constipation, or medications.[31] Although the evidence base for the treatment of nausea and vomiting in the palliative care population is limited, identification of causative factors can also guide rational drug therapy selection.[30,31] Causes of nausea and vomiting, and cause-directed therapies, are shown in Table e28-1. If the cause of nausea and/or vomiting is not identifiable or is multifactorial, dopamine antagonists such as haloperidol should be considered for the first-line therapy because most symptoms of nausea and vomiting are due to gastroparesis or irritation of the chemoreceptor trigger zone.[30] Little evidence supports the use of 5-HT$_3$ receptor antagonists outside of chemotherapy-induced and postoperative nausea/vomiting, and thus, these agents have a limited role in palliative care.[30] Because patients may have multiple causes of nausea and vomiting that respond differently to different agents, use of more than one antiemetic from different classes may be required.[30] If symptoms are refractory to first- or second-line therapy, olanzapine may be useful due to its effect on multiple neurotransmitters involved in the emetic pathway.[30] Nonpharmacologic therapies for nausea and vomiting include relaxation therapy and distraction, provision of small, frequent meals with adequate liquids, and acupuncture.[18]

TABLE e28-1

Causes of Nausea and Vomiting and Treatment

Cause of Nausea and Vomiting	Receptor Target	First-Line Treatment	Alternative Treatment
Chemical - Drugs: opioids, antimicrobials, antidepressants, antipsychotics - Metabolic: end-organ failure, electrolyte abnormalities - Toxins: disease-related (cancer), infection	- D_2 - 5-HT_3 - NK_1	Haloperidol	Ondansetron
Impaired Gastric Emptying - Drugs: opioids, tricyclic antidepressants, anticholinergics, phenothiazines - Ascites - Hepatomegaly - Tumor infiltration	- 5-HT_4 - D_2	- Metoclopramide - Discontinuation of causative drugs (if possible)	
Visceral or Serosal - Bowel obstruction - Constipation - Metastatic disease	- 5-HT_3 - ACh	- Promethazine - Diphenhydramine - Meclizine	Prochlorperazine
Cranial - Increased intracranial pressure - CNS tumors - Radiation therapy	- H_1 - Ach - 5-HT_3 - 5-HT_4 - NK_1 - Mu	Chlorpromazine promethazine	- Haloperidol - Dexamethasone
Vestibular - Drugs: opioids - Motion sickness	- H_1 - ACh	- Chlorpromazine - Promethazine - Diphenhydramine	- Scopolamine - Prochlorperazine
Cortical - Pain - Anxiety	- GABA - H_1	- Lorazepam - Treatment of underlying pain or anxiety, if applicable	

D_2, dopamine type 2 receptor; 5-HT_3, serotonin type 3 receptor; NK_1, neurokinin 1 receptor; 5-HT_4, serotonin type 4 receptor; ACh, acetylcholine receptor; H_1, Histamine type 1 receptor; Mu, μ-opioid receptor.

Data from References 30 and 31.

Anxiety

Anxiety is a common symptom among palliative care patients, and may be an underlying condition, caused by the serious illness itself or exacerbated by physical symptoms such as pain and dyspnea.[18] Communication with patients about their goals of care, and addressing spiritual concerns, discussed later in this chapter, are both essential components of managing anxiety in palliative care patients.[18] Other nonpharmacologic tools for managing anxiety, including relaxation techniques and psychotherapy, may also be useful.[18]

First-line pharmacologic therapy consists of benzodiazepines.[18] These agents may be combined with selective serotonin reuptake inhibitors (SSRIs), which have an anxiolytic effect in addition to their antidepressant activity. Because SSRIs do not achieve efficacy until 4 to 6 weeks after initiation, they are not appropriate for patients with a life expectancy of less than 1 month.[18]

Delirium

Delirium is an acute decline in attention and consciousness combined with cognitive dysfunction and is a common symptom among patients receiving palliative care.[18] Among palliative care patients, 13% to 42% of patients have delirium upon admission to a palliative care unit, 26% to 62% of patients have delirium at some point during their admission to a palliative care unit, and 59% to 88% of patients experience delirium during the final weeks preceding death.[32] While delirium may be of a hyperactive, hypoactive, or mixed subtype, hypoactive delirium is most common and also more difficult to detect.[32]

Although often considered an indicator that a patient is approaching the final weeks to days of life, it is important to note that nearly half of delirium cases may be caused by reversible factors and these causes should be assessed and reversed if possible.[18,32] Potentially reversible causes of delirium among palliative care patients include the following: uncontrolled pain; constipation; infections; electrolyte abnormalities; withdrawal from opioids, benzodiazepines, or alcohol; medication adverse effects; and lack of sleep.[18] When present, delirium can often be successfully managed or reversed; however, its presence is distressing to patients and caregivers, and can interfere with the assessment and management of other symptoms, such as pain.[32] Thus, the assessment of delirium is critical to provide good palliative care. Tools such as the Bedside Confusion Scale (BCS), Confusion Assessment Method (CAM), Delirium Rating Scale, and Memorial Delirium Assessment Scale are available to assist in the recognition of delirium and have been validated in the palliative care patient population.[32]

Nonpharmacologic management of delirium includes patient reorientation, maintenance of a sleep-wake cycle, provision of a familiar environment (presence of family), and provision of assistive devices such as a patient's glasses and hearing aids.[33] Pharmacologic management should begin with avoiding medications that can precipitate or worsen delirium such as benzodiazepines, opioids, anticholinergics, corticosteroids, and beta blockers, as well as correcting reversible causes of delirium.[18,33] Drug therapy for the prevention and treatment of delirium has not been supported by existing evidence.[33] While some pharmacologic therapies reduce the rates of delirium among hospitalized patients, an impact on clinical outcomes, such as length of stay and mortality, has not been demonstrated.[33] First- and second-generation antipsychotics are widely used for the management of delirium symptoms among palliative care patients which are not reversible; however, more evidence is required to fully support their place in therapy.[18,33]

MEDICATION MANAGEMENT

An essential component of providing quality palliative care is ensuring that the treatments a patient receives are consistent with his or her wishes and goals of care. Palliative care providers also have a responsibility to ensure that the benefits of any therapy provided outweigh the risks and burdens associated with that treatment.

Deprescribing, the process of discontinuing drug therapy with a goal of improving care and minimizing unnecessary polypharmacy is the one tool palliative care practitioners can use to achieve this aim.[34] Successfully applied, deprescribing can reduce the burden to patients due to the adverse effects of individual agents and also decrease the risks associated with polypharmacy such as drug interactions and use of potentially inappropriate medications.[34–37] When combined with palliative care, deprescribing has been shown to result in reduced medication burden, decreased mortality, reductions in hospitalizations, and improvements in patient-reported overall health.[34]

When evaluating medication regimens for candidates for deprescribing, practitioners should consider all drugs in a patient's regimen and the indication for each (if known).[34] Drug candidates for deprescribing include those without an indication, those whose potential harms outweigh potential benefits, drugs initiated to control adverse effects associated with another drug that may not be required, and preventive drugs whose benefit is unlikely to be realized given the patient's life expectancy.[34]

END-OF-LIFE CARE

⑥ As discussed earlier, palliative care can and should be provided in concert with curative efforts in patients with serious illnesses. At some point, curative therapies are no longer viable, but aggressive palliative care efforts should continue to the point of death.

The final days of life present special challenges for pharmacotherapy specialists. First, recognizing when the end is near is important. The "Investigating the Process of Dying" study evaluated physical signs in more than 350 terminally ill cancer patients.[38] Looking at 10 target physical signs, three were considered "early" signs (high frequency and moderate predictive value of death within 3 days): decreased level of consciousness (Richmond Agitation Sedation Scale score of –2 or lower), decreased performance status (Palliative Performance scale less than or equal to 20%), and dysphagia of liquids.[38] Associated symptoms include pulselessness on the radial artery, respiration with movement, decreased urine output, Cheyne-Stokes breathing, death rattle, periods of apnea, and peripheral cyanosis.

The National Cancer Institute provides a superb overview of the "Last Days of Life (PDQ)—Health Professional Version."[39] Much of this information is also applicable to imminent death for patients with noncancer diagnoses. This review covers those symptoms seen in the final months, weeks and days of life, care decisions during this time period, forgoing potentially life-sustaining treatments, and more. Issues of particular relevance for pharmacotherapy specialists include attention to symptoms likely to arise or worsen such as delirium, dyspnea, fatigue, pain, cough, death rattle, myoclonus, fever, and palliative care emergencies such as catastrophic hemorrhage.

Medication management issues at this point in the patient's life clearly include elimination of medications unlikely to provide benefit, and switching to nonoral routes of medication administration that are least likely to be invasive. For example, several opioids, lorazepam, dexamethasone, and haloperidol, are available as "intensol" formulations. An intensol is a highly concentrated oral solution of a medication, such as morphine 20 mg/mL oral solution. Generally speaking, up to 1 mL can be instilled in the buccal cavity even if the patient is unconscious (the upper body should be propped up to 30° from horizontal to prevent aspiration). Medication management needs during final days should be anticipated and discussed with the family members and caregivers well in advance.

GOALS OF CARE

⑦ A critically important part of all patient care, but particularly while providing palliative care is to determine the patient's goals of care. As a matter of fact, the most common reason for referral to palliative care services is to have the "goals of care" discussion.[40] Meaningful conversations about the goals of care lead to significantly better patient and family outcomes including enhanced quality of life, less use of nonbeneficial medical care near death, better goal-consistent care, positive family outcomes, and reduced costs.[41]

Determining the patient's and family's wishes and goals of care requires excellent communication among healthcare providers, the patient, and the patient's family. There are many models that may be used to facilitate these discussions. Bernacki and colleagues provide an excellent review and synthesis of best practices for communication about serious illness care goals.[41] They suggest a "conversation guide" that includes probing the patient's understanding of their illness ("What is your understanding now of where you are with your illness?") and determining how much information that patient would like to know about their illness ("How much information about what is likely to be ahead with your illness would you like from me?"). The model continues with questions that help shape goals, solicit patient/family fears and worries, assess important functional goals, determine how much information the patient wants to share with others, and explore the idea of "trade-offs." One suggested trade-off question is, "If you become sicker, how much are you willing to go through for the possibility of gaining more time?" This question may include advance directives such as "do not resuscitate" or "do not intubate" but also includes the patient's willingness to undergo potentially aggressive therapies such as continued chemotherapy, radiation, surgery, and hospitalization including intensive care unit admission. This conversation helps shape pharmacotherapy, frequently shifting from often futile curative therapies to supportive/palliative measures.

Kaldjian and colleagues reviewed the literature regarding goals of care at the end of life. They determined six overarching comprehensive goal categories most often brought up by patients: be cured, live longer, improve or maintain function/quality of life/independence, be comfortable, achieve life goals, and provide support for family/caregiver.[42] Again, the wish to "be comfortable" is highly relevant to pharmacotherapy specialists. Specific comfort goals that frequently populate a "top 10 wish list" for patients with a serious illness and may be related to drug therapy include: to be free from pain (number 1), to be mentally aware, not being short of breath, not being connected to machines, and to be free from anxiety.[43] Understanding the advanced illness patient's goals of care, and cultural beliefs is critically important in the medication management process.

SPIRITUAL CONSIDERATIONS

8 While physical comfort is paramount in caring for patients with advanced illnesses, nonphysical complaints such as spiritual concerns are an important component of total patient care. Palliative care providers span a range of healthcare disciplines, and it is critically important that all providers work collaboratively to achieve physical, psychological, social, and spiritual goals established by the patient. Spirituality is "the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and/or to the significant or sacred."[44]

Research has shown that a patient's religion and spirituality play an important role in coping with disease-related symptoms and affect the quality of life and medical decision making.[45] The National Consensus Project (NCP) provides "Clinical Practice Guidelines for Quality Palliative Care," emphasizing spiritual, religious, and existential aspects of advanced illness care as one of the key elements of palliative care.[46] Pharmacotherapy specialists should be competent to perform an initial spiritual screening, with subsequent referral to a board-certified chaplain as appropriate. One instrument that has been developed to assist primary care practitioners and other nonspecialists perform a spiritual assessment is the FICA (F—faith and belief; I—important; C—community; A—address in care) tool developed by Puchalski and colleagues.[47]

CONCLUSION

Palliative care provides patients with serious illness with symptom management, attention to quality of life, and alignment of treatment with patient-identified goals. Providing palliative care requires healthcare practitioners to be competent in the management of pain, dyspnea, constipation, and other symptoms using pharmacologic and nonpharmacologic treatments. Practitioners are also challenged to address the nonphysical needs of patients with serious illness including spirituality and faith. Lastly, palliative care practitioners must continually strive to ensure that all treatments provided to patients with serious illness are consistent with the patients' goals of care and are not associated with burdens that outweigh potential benefits.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is false regarding the concept of palliative care?

    A. Palliative focuses on pain and symptom management and other needs of the patient to achieve an optimal quality of life.

    B. Palliative care should not be combined with active or curative treatment of a serious or life-threatening illness.

    C. Palliative care often intensifies as a patient gets closer to end of life.

    D. Palliative care is a team approach that includes social, psychological, and spiritual support for the patient, caregiver, and family.

2. Nociceptive pain is best described by which of the following statements?

    A. Nociceptive pain is specific and well-localized.

    B. Nociceptive pain is described as a gnawing, cramping, aching, squeezing, pressure-like sensation.

    C. Opioids are useful in treating nociceptive pain.

    D. A and B

E. B and C

3. Which of the following statement(s) is/are *true* regarding dyspnea?

A. Dyspnea is a common end-of-life symptom that may evoke distress and anxiety in a patient.

B. Dyspnea may be defined as an unpleasant or uncomfortable sensation of breathing.

C. Dyspnea is objective and involves the patient's perception of the sensation and his or her reaction to it.

D. A and B only.

E. A, B, and C.

4. Respiratory sedatives are used to manage dyspnea at the end of life. Which of the following statements is/are false?

A. Opioids alter the perception of breathlessness.

B. Opioids decrease the ventilatory response to high oxygen and low carbon dioxide levels.

C. Benzodiazepines help to relieve anxiety associated with dyspnea.

D. Opioids cause vasodilation and can improve cardiac function.

5. Which of the following statements regarding dyspnea in patients receiving palliative care is false?

A. Dyspnea is difficult to manage at the end of life because the underlying cause can no longer be reversed.

B. Typical palliative treatments are opioids and benzodiazepines.

C. Nonpharmacologic approaches can be useful.

D. Oxygen therapy is useful unless hypoxia is present.

6. Which of the following is a preferred agent in patients in palliative care with nausea and vomiting of unknown etiology?

A. Metoclopramide

B. Haloperidol

C. Promethazine

D. Lorazepam

7. When selecting an appropriate antiemetic, which of the following factors should be taken into account?

A. The etiology of nausea and vomiting

B. Available routes of administration of therapy which are best for the patient

C. Potential adverse effects of medications

D. All of the above

8. A patient begins experiencing symptoms of delirium, including decreases in attention and cognition. Which of the following statements regarding delirium in patients receiving palliative care is correct?

A. Delirium cannot generally be controlled.

B. Delirium is frequently caused by reversible factors.

C. Delirium is rarely present in the final weeks of life.

D. Pharmacologic treatment of delirium is preferred over nondrug measures.

E. Hyperactive delirium occurs more frequently than hypoactive delirium.

9. Symptoms occurring in the last hours to days of life include which of the following?

A. Dysphagia, even with liquids

B. Delirium

C. Decreased level of consciousness

D. All of the above

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Rationale: Patients may receive palliative care throughout the course of a serious illness, including while the patient receives treatment aimed at managing or curing the disease.

2. **E.** Rationale: In comparison to the sharp pain associated with neuropathic conditions, nociceptive pain is commonly described by patients as achy, throbbing, and dull. Traditionally, nonopioid analgesics such as acetaminophen and nonsteroidal anti-inflammatory agents are often considered first line for pain management. However, among the palliative care patient population, the severity of pain or contraindications to nonopioid agents often necessitate the use of opioid agents such as morphine, oxycodone, or hydromorphone.

3. **D.** Rationale: Dyspnea is a subjective symptom that is common in the palliative care patient population.

4. **B.** Rationale: The beneficial effect of opioids on dyspnea is postulated to occur through multiple mechanisms: a vasodilatory effect on the pulmonary vasculature, a decrease in oxygen consumption during rest and exertion, and changes in the effects of carbon dioxide, oxygenation, and inspiratory flow resistive loading on ventilation.

5. **D.** Rationale: Oxygen is frequently requested by patients for symptoms of breathlessness, but it has not been shown useful for those without hypoxia. When underlying causes can be identified, they can be addressed, but reversal in patients at the end of life may not be possible. Opioids are first-line treatments for pharmacologic management of dyspnea, and benzodiazepines are second- or third-line agents. Nonpharmacologic approaches include fans, repositioning the patient, pulmonary rehabilitation, and complementary therapies.

6. **B.** Rationale: If the cause of nausea and/or vomiting is not identifiable or is multifactorial in the patient receiving palliative care, dopamine antagonists such as haloperidol should be considered for first-line therapy because most symptoms of nausea and vomiting are due to gastroparesis or irritation of the chemoreceptor trigger zone.

7. **D.** Rationale: When evaluating a patient's complaint of nausea and/or vomiting, the palliative care practitioner should attempt to identify the cause of nausea and/or vomiting to identify potentially reversible causes such as those due to hyperglycemia, electrolyte abnormalities, constipation, or medications. Although the evidence base for treatment of nausea and vomiting in the palliative care population is limited, identification of causative factors can also guide rational drug therapy selection. See Table e28–1 for medications useful for specific types of nausea and vomiting.

8. **B.** Rationale: In the final weeks of life, 59% to 88% of patients experience delirium. It is most often of the hypoactive type, which is more difficult to recognize than the other types of delirium. Because delirium is caused by reversible factors: uncontrolled pain; constipation; infections; electrolyte abnormalities; withdrawal from opioids, benzodiazepines, or alcohol; medication adverse effects; and lack of sleep—about half the time, these should be addressed when present. Delirium can often be successfully managed or reversed.

9. **D.** Rationale: Early signs of the end of life include decreased level of consciousness, decreased performance status, and dysphagia of liquids. Issues

identified in an NCI review of terminal symptoms that are of particular importance to pharmacotherapists include delirium, dyspnea, fatigue, pain, cough, death rattle, myoclonus, fever, and palliative care emergencies such as catastrophic hemorrhage.

Chapter e29: Evaluation of Cardiovascular Function

Brent N. Reed; Kristin Watson; Gautam Ramani

KEY CONCEPTS

KEY CONCEPTS

① Many cardiovascular disorders develop over years to decades. Evaluation of the patient with or at risk for cardiovascular disease (CVD) must therefore include a comprehensive patient (or caregiver) interview to identify traditional risk factors and risk-enhancing factors for CVD. Along with other key information (eg, vital signs, laboratory values), these data can be used to determine a patient's risk for future cardiovascular events.

② Changes in the frequency, duration, and severity of cardiac-related symptoms (eg, ischemic chest pain, dyspnea) are essential to the assessment of CVD and often guide the urgency of intervention as well as the specific pharmacologic strategies selected. A comprehensive patient interview can also be useful for discerning CVD from noncardiac disorders that share similar symptomology.

③ Obtaining an accurate blood pressure measurement is paramount to the evaluation and treatment of several cardiovascular disorders. Guidelines for appropriate measurement techniques include recommendations on patient preparation and position, cuff size, and blood pressure documentation.

④ Several cardiovascular disorders, such as heart failure (HF) and peripheral arterial disease, warrant physical examination of areas that are more distal from the heart, including the neck (eg, carotid arteries, jugular venous pressure, abdominojugular reflux) and lower extremities (eg, peripheral pulses, edema). Abnormal findings can prompt further evaluation or alterations in pharmacologic therapy.

⑤ Auscultation of the chest provides key information on valvular structure and function. Abnormal heart sounds can be used to guide the need for further evaluation.

⑥ Two key cardiac-specific laboratory tests are cardiac troponin and brain natriuretic peptide (BNP). Elevations in cardiac troponin may indicate the presence of myocardial infarction and can be used to guide both pharmacologic and nonpharmacologic interventions. A normal BNP concentration in a patient with dyspnea excludes the presence of HF, whereas elevations are correlated with disease severity as well as long-term morbidity and mortality.

⑦ An electrocardiogram (ECG) records the pattern of electrical activity across the heart and each segment corresponds to an event in the cardiac cycle. The ECG provides an electrical map of the heart, which can be used to locate areas of ischemia or other pathology and identify arrhythmias. Alterations in the ECG such as QT-interval prolongation can be drug-related and may place patients at risk of potentially life-threatening arrhythmias.

⑧ Stress testing remains the most common initial strategy for evaluating chest pain suspicious for myocardial ischemia. The two main modalities for testing are inducing stress via exercise or the administration of a pharmacologic agent such as dobutamine or adenosine. The information provided by a stress test is often combined with echocardiography and radionuclide myocardial perfusion imaging.

⑨ Echocardiography uses sound waves to create an image of the heart, providing important information on the structure and function of heart valves and chambers. Although a transthoracic echocardiogram (TTE) is less invasive and provides the key information necessary for most clinical decisions, a transesophageal echocardiogram (TEE) may be required to visualize structures located in posterior areas of the heart (eg, mitral valve, left atrial appendage) and to guide surgical planning.

⑩ Left heart catheterization (LHC) is an invasive procedure in which a catheter is inserted into a large artery and advanced to the left side of the heart. The most common indication for LHC is coronary angiography, in which radiocontrast dye is used to visualize the coronary anatomy, most often for evaluation of chest pain, concern for myocardial infarction, and abnormal stress testing, and to guide decision making regarding medical therapy, percutaneous coronary intervention, or coronary artery bypass grafting.

⑪ Right heart catheterization (RHC) involves advancing a catheter through a large vein and into the right side of the heart, where information on pulmonary and intracardiac hemodynamics can be obtained. Key parameters obtained during RHC include pulmonary artery pressures (including pulmonary capillary wedge pressure), cardiac output, and systemic and pulmonary vascular resistance, and these can be used to guide pharmacologic therapies in patients with HF or pulmonary hypertension.

⑫ Cardiac computed tomography (CCT) and cardiovascular magnetic resonance (CMR) imaging are noninvasive tests used to construct three-dimensional images of the heart. CCT can be used as an alternative to cardiac catheterization for performing coronary angiography, and CMR is commonly used to elucidate the etiology of HF.

BEYOND THE BOOK

BEYOND THE BOOK

The following activity will be useful for enhancing your understanding of the COLLECT and ASSESS steps of the patient care process. Tools you will need for this activity are a stethoscope and a pen and paper (or electronic device) for recording information. With a classmate, friend, or family member, conduct a focused interview to assess for traditional cardiovascular risk factors and risk-enhancing factors. If this information is not readily available, make note of how the data could be collected. Measure the heart rate using palpation and auscultation. When using the stethoscope, listen for S_1 and S_2 heart sounds and match them to the corresponding events in the cardiac cycle. If you have access to a blood pressure cuff, practice taking a blood pressure measurement according to the steps outlined in Table e29-4. Input the information you collected into an atherosclerotic cardiovascular disease (ASCVD) risk estimator such as this calculator (http://tools.acc.org/ASCVD-Risk-Estimator-Plus/) developed by the American College of Cardiology and American Heart Association. If your partner does not know their lipid profile, input normal and abnormal values (Table e29-6) to see how changes in serum cholesterol concentrations impact long-term ASCVD risk. To practice assessing for peripheral arterial disease, palpate the posterior tibial and dorsalis pedis and posterior tibial pulses (Fig. e29-3) and compare the strength of the pulses between both lower extremities. Finally, document all the data you collected as if it would be included in the medical record.

INTRODUCTION

Cardiovascular disease (CVD) remains the most common cause of death in the United States, and its incidence and prevalence continue to grow.[1] According to some estimates, the burden of treating CVD is expected to exceed $1 trillion by the year 2035.[2] Although some cardiovascular disorders emerge suddenly, most develop insidiously over the course of years and worsen with time. Additionally, many of the risk factors associated with CVD are either preventable or responsive to changes in lifestyle (eg, diet, physical activity). As a result of these and other factors, serial assessment of CVD is paramount to risk reduction and treatment.

Despite its deceptively simple role in circulating blood throughout the body, the cardiovascular system is quite complex. Each cardiac cycle represents a coordinated effort between the heart's electrical and mechanical systems, and a complex network of blood vessels provides the conduits through which oxygen and nutrients are delivered to tissues throughout the body and carbon dioxide and other waste products are transported away. Assessment of the cardiovascular system must therefore account for each of these physiological roles as well as how deficits in cardiac function may manifest elsewhere in the body, often necessitating a head-to-toe evaluation.

The purpose of this chapter is to introduce learners to the diagnostic and evaluative modalities used in the assessment of cardiovascular disorders. A particular emphasis has been placed on those procedures that have important implications for pharmacotherapeutic decision making. Learners are encouraged to use this chapter in conjunction with each of the chapters in the "Cardiovascular Disorders" section to discern how signs and symptoms, physical examination findings, and the results of these procedures alter the treatment of CVD. An overview of commonly used assessments in CVD is provided in Table e29-1.

TABLE e29-1

Overview of Commonly Used Assessments in Cardiovascular Disease[a]

Diseases (relevant chapters for more details)	Signs and Symptoms	Physical Assessment	Laboratory Findings	Other Modalities
Arrhythmias (Chapter 40, "Arrhythmias")	• Dizziness/lightheadedness • Dyspnea • Palpitations • Syncope	Heart rate and rhythm	None	• ECG • Echocardiogram
Dyslipidemia (Chapter 32, "Dyslipidemia")	Xanthomas	None	Lipid profile	None
Heart failure (Chapter 36, "Chronic Heart Failure"; Chapter 37, "Acute Decompensated Heart Failure")	• Dyspnea • Orthopnea • Bendopnea • Paroxysmal nocturnal dyspnea • Weight gain	• Abdominojugular reflux • Blood pressure • Heart rate and rhythm • Heart sounds • Lung sounds • Jugular venous pressure • Point of maximal impulse • Lower extremity edema (bilateral) • Lower extremity color, temperature, and pulses	• Brain natriuretic peptide • Biomarkers of end-organ function	• Cardiac catheterization • Chest x-ray • CMR imaging • Echocardiogram • Nuclear imaging (MUGA, PET, SPECT)
Hypertension (Chapter 30, "Hypertension"; Chapter e31, "Acute Hypertensive Crisis")	• Target-organ damage during hypertensive crisis may cause: • Headache • Altered vision • Chest or back pain • Dyspnea	Blood pressure	None	None
Ischemic heart disease[b] (Chapter 33, "Stable Ischemic Heart	Chest pain (angina)	None	• High-sensitivity C-reactive protein	• ECG • Cardiac

Disease"; Chapter 34, "Acute Coronary Syndromes")			- Cardiac troponin - Creatine-kinase myocardial band - Lipid profile	catheterization - CCT angiography - CMR imaging - Coronary artery calcification score - Stress testing - Myocardial perfusion imaging (PET, SPECT)
Peripheral arterial disease (Chapter e35, "Peripheral Arterial Disease")	Lower extremity pain	- Ankle-brachial index - Lower extremity bruit - Lower extremity color and pulses	None	None
Pulmonary hypertension (Chapter 46, "Pulmonary Arterial Hypertension")	Dyspnea	- Lung sounds - Abdominojugular reflux (if right heart failure present)	Brain natriuretic peptide (if right ventricular dysfunction present)	- Cardiac catheterization - Echocardiography
Stroke (Chapter 39, "Stroke")	- One-sided muscle weakness or paralysis - Speech abnormalities - Sudden vision changes - Dizziness/loss of balance	- Blood pressure - Carotid bruit - Heart rate and rhythm (atrial fibrillation)	None	- Brain imaging (CT, MRI) - Carotid Doppler - See Chapter 38, "Venous Thromboembolism" for more details
Valvular heart disease	- Dyspnea - Palpitations - Syncope	Heart sounds	None	Echocardiogram
Venous thromboembolism (Chapter 38, "Venous Thromboembolism")	- Dyspnea (pulmonary embolism) - Lower extremity pain (deep vein thrombosis)	- Lower extremity temperature - Lower extremity edema (unilateral)	- D-dimer - See Chapter 38, "Venous Thromboembolism" for more details	- Pulmonary imaging (CT, V/Q scan) - Lower extremity ultrasonography - See Chapter 38, "Venous Thromboembolism" for more details

[a] This table provides an overview of commonly used modalities, with an emphasis on those discussed in this chapter, which are used to assess the disorders covered

in this textbook, and is not intended to be comprehensive.

[b]Includes acute coronary syndromes.

CCT, cardiac computed tomography; CMR, cardiovascular magnetic resonance; CT, contrast tomography; ECG, electrocardiogram; MRI, magnetic resonance imaging; MUGA, multiple gated blood pool imaging; PET, positron emission tomography; SPECT, simple photon emission computed tomography; V/Q, ventilation/perfusion.

Medical History

① The interviewer should assess for the presence of traditional cardiovascular risk factors as well as risk-enhancing factors in all adult patients with or without established CVD (Table e29-2). Based on traditional risk factors and other patient-specific information, the 10-year risk for developing a first atherosclerotic cardiovascular disease (ASCVD) event can be determined in individuals aged 20 to 79 years by using the Pooled Cohort Equations Risk Calculator developed by the American College of Cardiology and American Heart Association (ACC/AHA) (http://tools.acc.org/ASCVD-Risk-Estimator-Plus/).[3] The 10-year risk of developing ASCVD may then be paired with an assessment of risk-enhancing factors to guide an individualized risk prevention strategy, such as determining the appropriate hypertension treatment, selecting lipid-lowering therapy, and identifying whether aspirin is indicated for primary prevention of CVD.[3-5] The identification of modifiable risk factors also provides clinicians with an opportunity to educate patients on therapeutic lifestyle changes that may also impact their risk of CVD.

TABLE e29-2

Major Cardiovascular Risk Factors and Risk-Enhancing Factors

Traditional Cardiovascular Risk Factors	Risk-Enhancing Factors
• Age • Sex • Race • High blood pressure • Elevated total cholesterol • Elevated LDL cholesterol • Low HDL cholesterol • Diabetes mellitus • Tobacco use • Overweight/obesity • Sedentary behavior • Diet (high saturated fats, low intake of fruit, vegetables, legumes, nuts, whole grains, and fish)	• Family history of premature cardiovascular disease in a first-degree relative (men <55 years of age; women <65 years of age) • Persistently elevated LDL cholesterol >160 mg/dL (4.14 mmol/L) • Chronic kidney disease (eGFR 15-59 mL/min/1.73/m^2 with or without albuminuria; not treated with dialysis or kidney transplantation) • Metabolic syndrome • Premature menopause (age <40 years) and pregnancy-associated conditions that increase the risk of ASCVD (eg, preeclampsia) • Chronic inflammatory diseases (eg, rheumatoid arthritis, HIV) • Ethnicity (eg, South Asian ancestry) • Persistently elevated triglycerides (>175 mg/dL [1.98 mmol/L]) • If measured, hs-CRP >2.0 mg/L, Lp(a) >50 mg/dL or >125 nmol/L, apoB >130 mg/dL [1.3 g/L], ankle-brachial index <0.9

apoB, apoprotein B; ASCVD, atherosclerotic cardiovascular disease; hs-CRP, high-sensitivity C-reactive protein; eGFR, estimated glomerular filtration rate; HDL, high-density lipoprotein; LDL, low-density lipoprotein; Lp(a), lipoprotein (a).

Data from References 3 and 5.

The presence of clinical ASCVD, often defined as coronary artery disease (CAD), aortic aneurysm, cerebrovascular disease, or peripheral arterial disease (PAD), should also be determined, as this information will guide the assessment and treatment approach. Finally, a thorough medication history is also important for identifying allergies or adverse events that may impact clinical decision making as well as medications that may cause or exacerbate CVD.[3]

Risk Factor Assessment

Family History

Genetics play a role in the development of many cardiovascular conditions, including premature CAD, heart failure (HF), and cardiac arrhythmias. Clinicians should inquire about the health status of all first-degree relatives, and document the presence of premature CVD, defined as a cardiovascular event in male relatives under the age of 55 and female relatives under the age of 65.

Social History

Current and prior use of alcohol, tobacco, and illicit substances should be characterized at each encounter, including both the quantity (eg, drinks per day) and duration (eg, cigarette pack-years) of use. Clinicians should counsel patients on appropriate alcohol limits based on gender and other characteristics (eg, comorbid conditions). An assessment of tobacco use should be performed at each patient encounter (see Chapter 86, "Substance Use Disorders II: Alcohol, Nicotine, and Caffeine" for details).[3,6] Finally, obtaining a thorough social history is also important for identifying social determinants of health and other barriers to care (eg, education level, ability to afford medications).

Physical Activity

Patients should be questioned regarding the types and amounts of physical activity in which they engage on a daily and weekly basis.[3] Clinicians should assess factors that may limit or preclude a patient from engaging in physical activity, as these may indicate the presence or worsening of a cardiovascular condition (eg, HF, PAD).[7,8] An assessment of functional status in those with physical limitations can be performed by asking patients about their ability to complete activities of daily living (eg, bathing, dressing) and instrumental activities of daily living (eg, cleaning, cooking).

SIGNS AND SYMPTOMS OF ORGAN DYSFUNCTION

② In addition to performing a past medical history (including prior cardiac tests and procedures) and identifying risk factors for CVD, a comprehensive patient history should also include an assessment of symptoms. When performed correctly, clinicians can often assess the severity and stability of disease without the use of expensive laboratory or diagnostic tests. The OPQRST (Onset, Provocation/Palliation, Quality, Region/Radiation, Severity, and Time) mnemonic can be a helpful guide to symptom assessment. The following sections provide an overview of common signs and symptoms in patients with CVD (as summarized in Table e29-1).

Chest Pain

Chest pain can occur for many reasons, requiring that the clinician distinguish cardiac and noncardiac etiologies (eg, pulmonary embolism [PE], gastroesophageal reflux disorder, costochondritis, panic attack) (Tables e29-2 and e29-3). Ischemic chest pain (ie, angina) typically begins in the retrosternal area and may radiate to the neck, jaw, and one or both arms. Ischemic chest pain may also be accompanied by nausea, dyspnea, diaphoresis, syncope, or abdominal pain. Atypical symptoms (eg, pleuritic chest pain, epigastric pain, unexplained acute or worsening dyspnea) may also be present, and these are more common in women and in patients with impaired renal function, diabetes, or dementia. Consequently, ischemia should not be ruled out in the absence of chest pain. The onset, duration, provocation, and palliation of symptoms must be ascertained to determine if the pain is stable or unstable. Pain that is new, occurring at rest, or worse compared to chronic pain is considered unstable. An electrocardiogram (ECG) should be performed in patients presenting with chest pain or other symptoms concerning for an acute coronary syndrome.[9]

TABLE e29-3

Characteristics of Ischemic Chest Pain

Characteristics	Not Characteristics
• Deep, poorly localized pain in chest and/or arm(s) • Reproducible with exertion or emotional stress, or develops at rest or with less exertion than the activity that previously precipitated the pain[a] • Begins in the retrosternal area • Relieved, in 5 minutes or less, with rest and/or short-acting nitroglycerin	• Pleuritic chest pain (provoked by respiration or cough and described as sharp or knifelike) • Localized to the middle or lower abdomen • Localized by the tip of one finger, specifically at the site of the left ventricular apex or costochondral junction • Reproduced with movement or palpation of chest or arms • Lasts less than a few seconds • Maximum intensity at onset • Radiates to the lower extremities

[a]Pain in those presenting with an acute coronary syndrome may have more severe and prolonged symptoms.

Data from Reference 9.

Nonischemic causes of chest pain include pericarditis, aortic dissection, and PE. Pericarditis, or inflammation of the pericardium, can cause sharp, pleuritic chest pain that can be partially or completely relieved by sitting up and leaning forward. Patients with a Type A aortic dissection (a tear beginning in the ascending aorta) most commonly present with chest pain in the anterior region, although some may present with posterior chest pain and/or abdominal pain. Those with a Type B dissection (a tear in the descending aorta) most commonly report back pain, although chest and abdominal pain are also frequently reported. Accordingly, an aortic dissection should not be ruled out in the absence of chest pain.[10]

Dyspnea

Dyspnea can occur with physical activity, termed “dyspnea on exertion,” or at rest. As with chest pain, clinicians must differentiate cardiac (eg, HF) and noncardiac etiologies (eg, chronic obstructive pulmonary disease, PE, pneumonia, and anemia). Patients should be asked about the activities they can perform before shortness of breath (SOB) occurs, such as the distance walked (eg, number of city blocks) or stairs climbed. An assessment of dyspnea also includes a characterization of the chronicity of symptoms, how they have changed over time, and their impact on the patient’s functional status, including activities of daily living.

Dyspnea that occurs when patients are in the recumbent position is known as orthopnea, a finding common in patients with HF due to changes in volume distribution and pulmonary pressures. The severity of orthopnea can be quantified by the number of pillows or the degree of elevation of the head needed to rest or sleep comfortably. In severe cases, patients may need to sleep in an upright position. Clinicians should explain the rationale for inquiring about the elevation of the head to differentiate it from other types of discomfort that may alter sleeping position (eg, neck or back pain). Alternatively, patients may be asked if they can sleep comfortably when lying flat and if not, the reason(s) why.

Paroxysmal nocturnal dyspnea (PND) refers to sudden episodes of dyspnea that present after the patient has been asleep for a few hours. The patient is often awakened from sleep and must sit or stand upright to relieve the SOB. Clinicians should document the number of PND episodes that occur per week or per night, as increasing frequency may indicate the presence of advanced disease.

Bendopnea is dyspnea that occurs when a person bends forward at the waist. Patients may experience bendopnea when bending over to put on socks or shoes and may purposefully wear slip-on footwear to avoid this symptom. Bendopnea is associated with a risk of HF hospitalization and clinical worsening in patients with pulmonary arterial hypertension (PAH).[11,12]

Various rating scales exist to grade the severity of dyspnea in patients with HF, and these can be used to track changes in symptoms over time. Although the Kansas City Cardiomyopathy Questionnaire and Minnesota Living with Heart Failure Questionnaire are used to characterize dyspnea in clinical trials, the severity of dyspnea in HF is most commonly graded according to the New York Heart Association (NYHA) classification system.[13,14] The NYHA class is important for determining an appropriate treatment strategy in patients with chronic HF (see Chapter 36, “Chronic Heart Failure”).[15] An analogous scale, the World Health Organization functional class, is imperative for designing a treatment plan for patients with pulmonary hypertension (see Chapter 46, “Pulmonary Arterial Hypertension”).[16]

Patients with a PE may also present with dyspnea accompanied by chest pain, cough, and tachycardia. Therefore, dyspnea should be evaluated in context with other subjective and objective data to determine its underlying etiology.

Syncope

Syncope is an abrupt, transient, and complete loss of consciousness attributable to the loss of postural blood pressure (BP). Although loss of consciousness is followed by rapid and spontaneous recovery, patients are often unable to brace themselves for the fall, and trauma to the face often occurs. Syncope is the result of decreased cerebral perfusion, and cardiovascular etiologies include bradycardia, tachycardia, and hypotension due to valvular heart disease, vasodilation, or acute vascular dissection.

Patients presenting with syncope should be assessed for orthostatic hypotension, a condition in which shifts from a supine to an upright position are accompanied by a decrease in systolic blood pressure (SBP) of ≥20 mm Hg and/or a decrease in diastolic blood pressure (DBP) of ≥10 mm Hg. Orthostatic hypotension causes syncope when patients are in the upright position. The effect of positional changes on heart rate should also be evaluated, and electrophysiological testing should be performed when the suspected etiology is a brady- or tachyarrhythmia, as syncope may be a sign of a potentially life-threatening dysrhythmia. A pacemaker may be indicated for those with irreversible causes of bradycardia whereas medication therapy and/or cardiac ablation may be considered in patients who develop syncope secondary to a tachyarrhythmia. Syncope in the presence of severe aortic stenosis is associated with a poor prognosis and dictates the need for surgical or transcatheter valve replacement in suitable candidates. Noncardiac causes of syncope or loss of consciousness include dehydration, blood loss, alcohol or drug intoxication, and seizure.[17]

To determine the underlying etiology of loss of consciousness and an appropriate treatment approach, the relationship between the time of the event to meals, physical activity, and medication administration should be ascertained. Patients should also be asked if they experienced a prodrome (eg, nausea, vomiting, feeling warm), as this is uncommon in syncope of cardiovascular etiology. One exception is vasovagal syncope, a common form of reflex syncope, which may occur as a result of vasopressor-dependent hypotension and/or inappropriate bradycardia. Vasovagal syncope may occur when patients are upright or in any position when provoked by stress or pain. Patients will typically experience warmth, nausea, diaphoresis, and have a pale appearance; fatigue often follows. Triggers and/or a prodrome can often be identified, although less commonly in older patients.

A complete medication history is imperative in the assessment of syncope. When possible, a report of the event should be obtained from bystanders. Clinicians should also assess for the presence of any nonsyncopal conditions that may cause self-limited loss of consciousness, including seizures, hypoglycemia, and intoxication, among others. An electroencephalogram should be obtained when a concern for seizures exists, such as when prominent jerking muscle movements are observed.[17]

Palpitations

The term *palpitation* refers to the awareness of one’s heartbeat. Patients may report feeling a pulsation or movement in the chest or adjacent areas and often describe it as being alarming and unpleasant or uncomfortable. The mechanism by which this sensation occurs is not well-defined. Cardiac awareness is normal if it occurs during activities that are typically associated with increases in the frequency and strength of cardiac contraction, such as physical activity or emotional stress. Palpitations of a cardiac origin include arrhythmias and structural heart disease (eg, severe mitral or aortic regurgitation and hypertrophic cardiomyopathy). An ECG can be performed to distinguish innocuous arrhythmias (eg, premature atrial contractions) from those requiring further evaluation. The absence of an arrhythmia should prompt an investigation of alternative causes, which may include medications (eg, anticholinergics, vasodilators), recreational drug abuse (eg, cocaine, amphetamines), caffeine, psychosomatic causes (eg, anxiety, panic attacks), and systemic diseases (eg, hyperthyroidism, anemia).[18] Patients may have more than one cause of palpitations.

Lower Extremities

Pain in the lower extremities may indicate the presence of PAD. If present, the location of the pain reflects the artery or arteries affected. To ascertain a cause of lower extremity pain, clinicians should assess its location; the effect of exercise, rest, and changes of position; and other associated characteristics. Patients with PAD can present with “classic” intermittent claudication symptoms, which consist of localized pain, discomfort, or fatigue that occurs in one or both lower extremities with physical exertion and is relieved within 10 minutes of rest. Atypical symptoms include pain that lingers after rest. Patients should be questioned regarding the presence of nonhealing wounds and ulcers as well as an altered sensation or a dusky appearance in the toes. Pain at rest can be a sign of chronic limb-threatening ischemia. However, non-exertional pain is rarely of cardiovascular origin and may instead be due to arthritis or nerve root compression. Pain or discomfort associated with swelling may be the result of venous insufficiency or deep vein thrombosis.

The presence of PAD should not be excluded in patients who deny exertional leg pain, as a significant proportion are asymptomatic.[19] Additionally, the walking distance may be limited by reasons other than PAD and thus preclude the development of pain. As a result, physical examination of the lower extremities is of paramount importance in patients at risk for PAD, as the presence of the condition increases the risk of ASCVD events and should serve as a target for risk reduction strategies (see Chapter e35, "Peripheral Arterial Disease" for details).[8]

PHYSICAL ASSESSMENT

Vital Signs

Blood Pressure

③ Recommendations for obtaining a BP in the office are provided in Table e29-4. Inaccurate measurements may result from failing to place patients in the correct position, using the wrong cuff size, and/or using a device that has not been validated. Use of an oscillometric device is preferred whenever possible to avoid some of the limitations of auscultatory BP assessment (eg, inflating or deflating the cuff too rapidly). These devices detect oscillations in pulsatile blood volume during cuff inflation and deflation. The use of an automated cuff is preferred.

TABLE e29-4

Recommendations for the Measurement of Blood Pressure in Humans

Steps to Measure BP	Instructions
Step 1: Prepare the patient in the proper position.	• The patient should be relaxed, seated in a chair with the back upright, feet on the floor, and not moving for at least 3 to 5 minutes. • The patient and healthcare professional should not talk during this time period. • The patient should have an empty bladder. • Caffeine, exercise, and smoking should be avoided 30 minutes before the measurement. • Clothing covering the location of the cuff should be removed; sleeves should not be rolled up.
Step 2: Use the proper BP measurement technique.	• Use a calibrated and validated upper arm device. • Support the patient's arm. The patient should not hold their arm. • Determine and use the correct cuff size. The bladder length should encircle 75-100% of the arm; the bladder width should be 37%-50% of the arm circumference. • Measure the arm circumference at the acromion and olecranon midpoint. • If the auscultatory approach is used, use the bell or diaphragm of the stethoscope.
Step 3: Take the proper measurements.	• Record the BP in both arms at the first visit. The arm that gives the higher reading should be used for subsequent visits. • Repeated measures should be separated by 1-2 minutes. • If the auscultatory approach is used: ○ Palpate the estimate of the radial pulse obliteration pressure to estimate the SBP. ○ Inflate the cuff to 20-30 mm Hg above the obliteration point. ○ Deflate the cuff pressure at 2 mm Hg per second and listen for the Korotkoff sounds. ○ The SBP is the onset of the first two consecutive beats and the DBP is the last sound heard.
Step 4: Document the BP readings.	• Document the SBP and DBP. • Record the time at which any BP medications were taken prior the readings.
Step 5: Average the readings.	• Estimate the patient's BP using the average of two or more readings on two or more occasions to determine the patient's BP.
Step 6: Provide readings to the patient.	• Share the BP readings with the patient, both orally and in writing. • Results should be interpreted for the patient.

BP, blood pressure; SBP, systolic blood pressure; DBP, diastolic blood pressure.

Data from Reference 25.

Blood pressure should be measured on two to three different occasions to determine an accurate estimate and minimize random error.[5,20] Although a "normal" adult BP is defined as an SBP <120 mm Hg and a DBP <80 mm Hg, readers are referred to Chapter 30, "Hypertension," for a full discussion of the thresholds at which hypertension is diagnosed as well as specific BP goals. Orthostatic hypotension should be routinely assessed for in older patients and those in whom postural changes result in dizziness, lightheadedness, blurry vision, or cognitive impairment. To assess for orthostatic hypotension, BP should be measured in the seated or supine position and then again after 3 minutes of standing.[17,20]

The use of home blood pressure monitoring (HBPM) or ambulatory blood pressure monitoring (ABPM) is recommended to confirm the diagnosis of hypertension and to titrate blood pressure–lowering medications. Up to 30% of patients may have "white coat" hypertension, in which BP is higher in the office than at home.[20-23] Out of office BP assessment can also detect masked hypertension, a scenario in which BP is normal in the office but high at home. Finally, ABPM can be used to evaluate those with labile hypertension and postural hypotension and determine the extent of, if any, variations in BP throughout the day and night.[5,24] Further information on when to utilize HBPM and ABPM is discussed in Chapter 30, "Hypertension."

Patients should be trained before using HBPM or ABPM. With HBPM, patients should prepare for each measurement according to the recommendations outlined in the first step of Table e29-4. Clinicians should help patients determine the most appropriate device for their needs, including measuring and noting the patient's arm circumference should they need to purchase their own device. A device with the ability to store readings is preferred, although patients can also log their readings manually. Patients should measure their BP each day and are encouraged to obtain multiple readings daily, such as in the morning prior to taking medications and at suppertime. At a minimum, BP should be measured weekly, two weeks after a change in BP regimen, and the week of the next appointment.[5] Additional information for patients who self-monitor their BP is available on the American Heart Association website (https://www.heart.org/en/health-topics/high-blood-pressure/understanding-blood-pressure-readings/monitoring-your-blood-pressure-at-home).

An ABPM device measures BP every 15 to 30 minutes during the day and every 15 to 60 minutes during the night and readings may be obtained over periods of 24 hours or more. Monitors are worn on a belt or carried in a pouch, allowing patients to engage in normal daily activities. However, patients should keep their arm still while the cuff is inflating.[24] A list of validated ABPM monitors is available at www.dableducational.org. Devices should be calibrated approximately every 1 to 2 years, according to the manufacturer's instructions.[25]

Pulses

The radial artery should be palpated to assess heart rate and rhythm. The tips of the index and middle fingers should be used (not the thumb). In patients with a regular rhythm, heart rate can be measured for 15 seconds and then multiplied by four to determine the number of beats per minute. In those with an irregular rhythm, the rate should be measured for 30 seconds to ensure that variations are accounted for; this rate should then be multiplied by two. The strength of the radial pulses should be compared on both sides. When a delayed arterial pulse is suspected, the heart should be auscultated while palpating the radial artery.

In adults, a normal resting pulse rate is 60 to 100 beats per minute (bpm). A rate of <60 bpm is referred to as bradycardia, whereas a rate of >100 bpm is referred to as tachycardia. Bradycardia may be physiologically normal in athletic individuals, or it may be the result of medications, hypothyroidism, or heart block. Any irregularities in heart rhythm should be documented. Examples of irregular rhythms include atrial flutter, in which intervals are similar and predictive (often termed "regularly irregular"), and atrial fibrillation, in which the intervals are not predictive or repetitive (termed an "irregularly irregular" rhythm). An ECG is necessary to confirm the presence of an arrhythmia, as the diagnosis cannot be made on physical examination findings alone.

Inspection

Jugular Venous Pressure

④ The jugular venous pressure (JVP) is an estimate of the central venous or right atrial (RA) pressure. The elevation of JVP, reported in cm, is determined as the distance between the sternal inflection point and the top of the jugular pulsation. The sternal inflection point or the angle of Louis is where the manubrium and the sternum intersect (Fig. e29-1). The internal jugular (IJ) is preferred over the external jugular (EJ) vein for inspecting JVP, as the IJ is directly in line with the superior vena cava and the RA. The presence of valves in the EJ and the potential for the vein to thrombose in older patients can also alter the interpretation of JVP.

FIGURE e29-1

Estimation of the jugular venous pressure. The distance between the base of the right atrium (RA) and the angle of Louis or sternal inflection point is 5 cm. In this figure, the top of the jugular venous pulse is 1 cm higher than that angle of Louis. The jugular venous pressure would be reported as 1 cm above the sternal notch and thus a total of 6 cm above the RA. (RV, right ventricle.) *(Reproduced, with permission, from Hammer GG, McPhee SJ. Pathophysiology of Disease: An Introduction to Clinical Medicine. 8th ed. New York: McGraw Hill; 2019.)*

Copyright © McGraw Hill. All rights reserved.

The JVP is determined by placing the patient at a 30 to 45-degree angle and reporting the number of centimeters above the sternal notch at which pulsation occurs (eg, "4 cm above the sternal notch"), or the observed distance plus 5 cm (eg, "a JVP of 9 cm"), which accounts for the estimated distance between the RA and the sternal notch. A JVP more than 4 cm above the sternal notch (more than 9 cm between the base of the RA and sternal notch) is considered elevated. The inability to detect a JVP on inspection should be reported as "not observed" (rather than "absent"), as any elevation between the top of the RA and the sternal inflection point cannot be observed.[26]

Extremities

Inspection of the skin on the lower extremities is useful for detecting the presence of PAD. Findings suggestive of severe limb ischemia include dependent rubor and elevated pallor. Dependent rubor refers to redness in the feet and toes when the legs are hanging from an elevated surface, whereas elevation pallor is a pale or ashen appearance in the lower extremities after they have been elevated at more than a 60-degree angle for greater than 60 seconds while the patient is in a supine position. Gangrene and nonhealing wounds or ulcers are signs of chronic limb ischemia and should prompt further evaluation. Wounds suggestive of PAD often occur distally, and cracked skin or fissures at the heel may also occur. The absence of leg hair is not diagnostic for PAD but should be considered when hair loss occurs unilaterally or when other features suggestive of the disease are present.[8,27]

Palpation

Carotid Pulses

To assess the carotid arteries, patients should be instructed to turn their head slightly and relax the neck muscles. The carotid pulse and rhythm should be evaluated on either side with gentle pressure using the index and middle fingers, but at separate times to prevent syncope. A normal carotid pulse is smooth and has a relatively quick upstroke and a more gradual downstroke. *Pulsus alternans* is a regular pulse at alternating strengths and is considered a sign of HF. A delayed upstroke and weak pulse (*pulsus parvus et tardus*) suggest aortic stenosis whereas aortic regurgitation may be observed as a Corrigan's or a water-hammer pulse, where the pulse is bounding with an abrupt expansion followed by a sudden collapse. Further evaluation is warranted in those with abnormal findings.[28,29]

Abdominojugular or Hepatojugular Reflux

Abdominojugular or hepatojugular reflux is often evaluated at the same time as JVP, while the patient is still positioned at a 45-degree angle. Pressure is applied to the middle or upper quadrant of the abdomen and held for at least 10 seconds and up to a minute. The test is considered positive if the JVP remains elevated while pressure is applied, indicating that the RA is unable to accommodate an increase in venous return, a finding suggestive of right-sided HF, constrictive pericarditis, or cardiac tamponade.[26,30] In many patients, a brief rise and fall in JVP will occur when pressure is initially applied but this is considered a negative finding.

Thrill

A thrill is a sensation that may be felt at the site where a bruit or murmur is heard and is indicative of significant turbulence in blood flow. A thrill is used in the definition of murmurs graded 4 or higher (discussed in detail in the section on auscultation).

Point of Maximal Impulse

The point of maximal impulse (PMI) refers to the area of the chest where the cardiac impulse is felt most strongly. A normal PMI is located at the fifth intercostal space at the mid-clavicular line (Fig. e29-2, in the area denoted “5”). When palpated, a single impulse should be felt with each cardiac cycle and the PMI should be approximately 2 cm in diameter. The PMI may be challenging to palpate in patients who are obese or muscular. In patients with dilated cardiomyopathy, the PMI is shifted laterally to the left. A PMI larger than 2 cm may be indicative of a hypertrophic or dilated left ventricle. A forceful and hyperdynamic impulse may suggest the presence of a hypermetabolic state such as severe anemia or hyperthyroidism, or it may be evidence of mitral regurgitation.

FIGURE e29-2

The five typical areas for cardiac auscultation. 1, aortic valve; 2, pulmonic valve; 3, accessory aortic area; 4, tricuspid valve; 5, mitral valve (also where the point of maximal impulse is normally located). *(Reproduced, with permission, from Fuster V, Harrington RA, Narula J, Eapen ZJ, eds. Hurst’s the Heart. 14th ed. New York, NY: McGraw Hill; 2017.)*

Extremities

Temperature: Comparing temperatures at multiple points between the two legs can be useful in detecting abnormalities. Cool extremities may be a sign of low cardiac output in HF or arterial insufficiency, whereas localized warmth, swelling, and redness may indicate the presence of a deep vein thrombosis.

Pulses: The femoral, popliteal, dorsalis pedis, and posterior tibial pulses are displayed in Fig. e29-3A. The strength of the pulses on both sides of the body should be directly compared. The popliteal artery should be palpated with the patient in the seated and supine positions as it can be difficult to find. The absence of pulses is not specific for PAD, as one or both dorsal pedis pulses may be absent in up to 17% of patients, and one or both posterior tibial pulses may be absent in up to 9%.[31] However, the absence of these pulses in combination with a femoral bruit is suggestive of PAD.[32]

FIGURE e29-3

Assessment of the lower extremity arteries. (*A*) Major arteries of the leg; (*B*) ankle-brachial index assessment.

Recommendations for grading the strength of pulses are as follows: 0, absent; 1, reduced; 2, normal; and 3, bounding. Clinicians are encouraged to document both the numeric grade and its definition, as various scales have been used for grading.[27] Findings suggestive of PAD should prompt additional testing to confirm the diagnosis.

The ankle- or toe-brachial index (ABI or TBI) is a simple, noninvasive test that can be used to diagnose PAD (Fig. e29-3B).[8] The ABI is the ratio of the SBP measured at the ankle to the SBP measured in the arm. The patient is placed in a supine position and pressures are obtained at the sites of the brachial, dorsalis pedis, and posterior tibial arteries using a Doppler ultrasound device. The ABI is calculated using measurements on both sides of the body, and the higher of the two ankle pulses is divided by the higher of the two brachial artery readings (Fig. e29-3B). An ABI ≤0.9 is generally considered abnormal.[8] Readers are referred to Chapter e35, “Peripheral Arterial Disease” for additional details.

Edema

Edema in the lower extremities can occur as a result of several different mechanisms. In some cases, the cause can be differentiated by the presence of pitting (ie, an indentation that remains after pressure is applied). In patients with HF, pitting edema occurs primarily as a consequence of increased hydrostatic pressure. Noncardiac etiologies of edema resulting from increased hydrostatic pressure include pregnancy, venous obstruction, and renal failure. Edema may also occur as a result of decreased oncotic pressure due to low plasma protein concentrations in conditions such as nephrotic syndrome, advanced liver disease, and malnutrition. Increased capillary permeability due to sepsis, burns, chemotherapeutic agents, or other factors can cause nonpitting edema, which tends to be more widespread rather than localized to the abdomen or lower extremities. Lipedema, or pathologic accumulation of fluid in adipose tissue, typically occurs in the upper torso and lower extremities, with the exception of the feet and ankles. Lymphedema, an accumulation of fluid that results from lymphatic obstruction, can appear in the upper or lower extremities and may be unilateral. Early stages have been described as being doughy in appearance, followed by thickened, fibrotic, hyperkeratotic skin later on. A variety of medications can cause edema as well.[33,34]

Clinicians should assess for the presence of edema in both legs starting in the ankle area. When present, the clinician should continue to palpate progressively higher up the leg and note the area to which the edema extends. Male patients with edema extending to the thighs should be asked about the presence of scrotal edema. Sacral edema should be assessed in those with edema extending to the top of the leg.

The presence of ascites should also be determined even in the absence of lower extremity edema. Patients should be asked if they have observed changes in abdominal girth and the duration over which any changes have occurred. For example, patients can be asked if they have had to loosen their belt or experienced recent increases in pant size. Further questioning can enable one to determine if changes in abdominal girth are secondary to volume changes or an increase in weight due to caloric intake.

Lower extremity edema is a common finding in patients with HF but volume overload should not be completely ruled out in patients with normal findings on palpation. When edema is present, it is typically bilateral and pitting in nature. Several systems exist for grading the severity of edema; most commonly, pitting edema is graded on a scale of 1+ to 4+. A score of 1+ indicates edema that is ≤2 mm in depth and rapidly disappears (sometimes referred to as "trace" edema); 2+ indicates edema that is 2 to 4 mm deep and disappears in 10 to 15 seconds; 3+ indicates edema that is 4 to 6 mm deep and lasts for a minute or more; and 4+ indicates edema >6 mm deep that lasts 2 minutes or more.

Unilateral edema is uncommon in HF and should prompt further evaluation. Potential etiologies include trauma, venous insufficiency, removal of veins (eg, coronary artery bypass graft [CABG] surgery), deep vein thrombosis, and infection.

Auscultation

Heart Sounds

⑤ Auscultation should occur over each valve area indicated in Fig. e29-3, using both the bell and diaphragm of the stethoscope. Heart sounds are designated S_1 through S_4; in adults, S_1 and S_2 are normal whereas S_3 and S_4 indicate the presence of pathologic conditions. Low-frequency sounds such as S_3 and S_4 are best heard using the bell of the stethoscope whereas high-frequency sounds, such as S_1 and S_2, are best heard using the diaphragm. The rate and rhythm of the heart should also be assessed during auscultation, as it may provide a more accurate assessment than palpation of the radial pulse alone.

S_1 – The first heart sound, S_1, is produced by the closure of the mitral and tricuspid valves. This sound occurs at the beginning of systole and is best heard at the left lower sternal border. The intensity of S_1 is diminished in those with severe mitral stenosis, as well as in patients who are mechanically ventilated or have obstructive lung disease, as the presence of air in the lungs limits the ability of sound to travel.[35]

S_2 – The second heart sound, S_2, is produced by the closure of the aortic and pulmonic valves. This sound indicates the beginning of diastole and is best heard at the second left intercostal space.[35]

S_3 – The S_3 heart sound or "ventricular gallop" is produced when blood strikes a compliant ventricle during passive filling. This sound is best heard at the apex and occurs in the mid-third of diastole. The presence of an S_3 is a sign of HF, as it occurs when the right or left ventricle is dilated and filling at high pressures.[35]

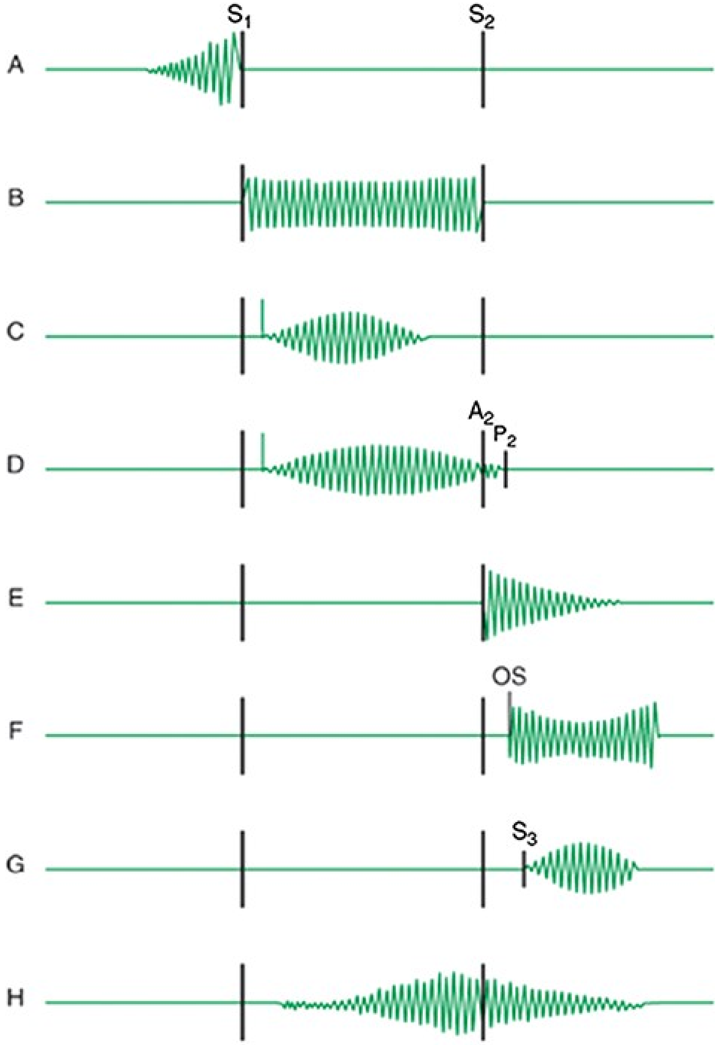
S_4 – The S_4 heart sound or "atrial gallop" occurs at the end of diastole, shortly before S_1, and is produced when the atria contract and blood strikes a non-compliant left ventricle. This sound may be heard in those with left ventricular hypertrophy secondary to hypertension, aortic stenosis, or hypertrophic cardiomyopathy.[35]

Murmurs – A murmur refers to the sound of blood as it passes through a heart valve. Some murmurs occur as the result of high flow across the valve or insignificant cardiac defects that are not pathologic in nature. Called innocent or flow murmurs, these sounds are usually soft and short in duration and have a "blowing" quality that may mimic the sound of ocean waves.

Murmurs may also be produced by turbulent blood flow through a heart valve and can indicate the presence and severity of valvular abnormalities. Murmurs are defined according to their timing within the cardiac cycle. Systolic murmurs are heard after the S_1 heart sound and before S_2, whereas diastolic murmurs are heard after S_2 but before S_1. Continuous murmurs extend across multiple phases of the cardiac cycle. A diagram of the principal heart murmurs is shown in Fig. e29-4.

FIGURE e29-4

(*A*), tricuspid or mitral stenosis—late, crescendo diastolic murmur; (*B*), mitral or tricuspid regurgitation—holosystolic murmur; (*C*), aortic ejection murmur that begins with an ejection click—crescendo-decrescendo systolic ejection murmur; (*D*), pulmonic stenosis—crescendo-decrescendo systolic murmur with a delayed closure of the pulmonic valve; (*E*), aortic regurgitation—early, decrescendo diastolic murmur; (*F*), mitral stenosis—decrescendo-crescendo mid-diastolic murmur occurring after the opening snap (OS); (*G*), third heart sound (S3) followed by a decrescendo-crescendo mid-diastolic inflow; (*H*), patent ductus arteriosus—continuous murmur. *(Reproduced, with permission, from Kasper DL, Fauci AS, Hauser SL, Longo DL, Jameson JL, Loscalzo J, eds. Harrison's Principles of Internal Medicine. 19th ed. New York: McGraw Hill; 2015.)*



Source: Joseph T. DiPiro, Gary C. Yee, L. Michael Posey, Stuart T. Haines, Thomas D. Nolin, Vicki L. Ellingrod: *DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e*
Copyright © McGraw Hill. All rights reserved.

Murmurs are further described by several other features. The duration of the murmur can be characterized as occurring early, mid, or late in a phase of the cardiac cycle or *holo* (throughout). For instance, a murmur from mitral regurgitation (Fig. e29-4B) is a holosystolic murmur. The configuration of the murmur, or changes in sound due to alterations in pressure, may also be described as crescendo, decrescendo, crescendo-decrescendo, or plateau. For example, an aortic ejection murmur (Fig. e29-4C) is a crescendo- decrescendo murmur, whereas a murmur from mitral regurgitation is a plateau. Additionally, the overall intensity of the sound of the murmur may be graded according to the criteria in Table e29-5. Finally, the location where the murmur originates and to where it radiates should also be described. For instance, a murmur consistent with aortic insufficiency (or regurgitation) originates at the second intercostal space, right sternal border, and an aortic stenosis murmur will often radiate into the carotid arteries as severity increases.

TABLE e29-5

Grade Scale for the Intensity of Murmurs

Grade	Criteria
I	Barely audible; no palpable thrill
II	Heard, not loud; no palpable thrill
III	Easily heard; no palpable thrill
IV	Easily heard; palpable thrill
V	Heard when the edge of the stethoscope touches the chest; a palpable thrill
VI	Heard with stethoscope off the chest; a palpable thrill

The presence of a new murmur warrants further evaluation by a cardiologist and potentially an echocardiogram to confirm the presence of a valvular abnormality. Prompt evaluation is also indicated when murmurs emerge or become more severe in the setting of worsening HF symptoms, new or worsening chest pain, or syncope, as valve replacement may be required.[35,36] A new murmur in the setting of infection, especially if accompanied by fevers and positive blood cultures, warrants immediate evaluation for endocarditis, as appropriate antibiotic treatment must be initiated quickly to prevent valve destruction and embolic complications.[37]

Pericardial Friction Rub

A pericardial friction rub is generated by friction between layers of inflamed pericardium and may be present in up to one-third of pericarditis cases.[38,39] To elicit the sound, patients should be asked to lean forward, increasing the area of contact between the visceral and parietal pericardium. A rub is present during both systole and diastole and is best heard over the left sternal border using the diaphragm of the stethoscope. The sound of a rub is harsh in nature and has been described as a “superficial scratchy or squeaking.”[40]

Bruit

A bruit is the sound generated by turbulent blood flow through an artery due to abnormal narrowing (ie, stenosis), and is usually heard during systole. A bruit heard over the carotid artery is suggestive of carotid stenosis but may be difficult to discern from aortic stenosis. A bruit over the femoral artery may indicate the presence of PAD or a vascular complication resulting from a mechanical intervention such as cardiac catheterization. When present, further evaluation is warranted. A bruit may be present in the abdominal area in the setting of an abdominal aortic aneurysm, but this finding is nonspecific and should not be used as the sole criteria for diagnosis.[41]

Lung

The lungs should be auscultated with the patient in the seated position using the diaphragm of the stethoscope. Patients should be encouraged to breathe through their mouth and should cough once to clear their chest prior to auscultation. The bilateral posterior chest is auscultated first, followed by the anterior chest. In healthy lungs, the only sounds heard should be air traveling in and out of the airways as the patient breathes.

Crackles (also known as rales) are a nonspecific finding characteristic of several cardiovascular and pulmonary conditions. Crackles can be heard on both inspiration and expiration and have been described as the sound of hair being rubbed together or the slow peeling of two pieces of Velcro apart. Crackles may be present in acute decompensated heart failure (ADHF) when the lung alveoli are filled with fluid. However, as volume status improves, crackles gradually disappear. Pulmonary causes of crackles include interstitial lung disease, pneumonia, and bronchitis.

Wheezing is a high-pitched whistling sound that typically occurs on expiration. Wheezing is a hallmark of asthma but may be heard in other lung conditions associated with airway obstruction, such as emphysema and bronchitis. Rhonchi are low-pitched, gurgling, or rattling sounds that can be heard both during inspiration and expiration. Rhonchi often suggest fluid or secretions in the large airways and may be heard in bronchitis or pneumonia.

Percussion of the lungs can assist in determining if a pleural effusion (a fluid collection between the lung and chest cavity) is present. A dull or thud-like sound can be heard over the area where the effusion is present, and it will gradually transition to a normal sound (like tapping a drum) at the meniscus of the effusion.[42,43]

LABORATORY FINDINGS

Biomarkers are measurements of biological function that can be used to diagnose certain conditions and assess the progress of a disorder or its response to pharmacologic therapy. In addition to cardiac-specific biomarkers, several noncardiac biomarkers are relevant to the assessment of CVD because they may influence risk or reflect alterations in heart function. Reference ranges for the laboratory values discussed in this section are displayed in Table e29-6.

TABLE e29-6

Common Laboratories Used in the Assessment of Cardiovascular Disease

Biomarker	Reference Range
Cardiac troponin[a]	
Troponin I	<0.01 ng/mL (mcg/L)
Troponin T	<0.04 ng/mL (mcg/L)
Creatine kinase–myocardial band (CK-MB)[a]	
Women	≤4 ng/mL (mcg/L)
Men	≤8 ng/mL (mcg/L)
Natriuretic peptides[b]	
Brain natriuretic peptide (BNP)	<100 pg/mL (ng/L; 29 pmol/L)
N-terminal proBNP (NT-proBNP)	<300 pg/mL (ng/L; 35 pmol/L)
High-sensitivity C-reactive protein (hs-CRP)	
Low risk	<1.0 mg/L
Intermediate risk	1.0-3.0 mg/L
High risk	>3.0 mg/L
Blood lipids[b]	
Total cholesterol	<200 mg/dL (5.17 mmol/L)
Triglycerides	<150 mg/dL (1.70 mmol/L)
Low-density lipoprotein (LDL)	<100 mg/dL (2.59 mmol/L)
High-density lipoprotein (HDL)	>40 mg/dL (1.03 mmol/L)

[a] May vary depending on individual clinical laboratory.

[b] Reference values provided; goals may differ in an individual patient.

Troponin

⑥ Cardiac troponin is an intracellular protein released into the bloodstream when myocardial necrosis occurs. Compared to troponin C, the troponin I and T subunits are more specific for cardiac tissue and are therefore useful indicators of myocardial injury. Since most assays are capable of detecting circulating troponin in healthy individuals, the 99th percentile of the upper reference level is recommended as the threshold at which myocardial infarction (MI) should be suspected.[44]

An elevation in troponin can be detected within 2 to 4 hours of myocardial necrosis, making it the preferred biomarker for supporting the diagnosis of MI. The absence of cardiac troponin using most modern assays has a negative predictive value for MI approaching 100%.[9] However, given the delay in troponin release following an MI, patients with ischemic symptoms who have a normal troponin on initial presentation should have it measured again 3 to 6 hours later. If an elevation is detected, a series of troponin tests should be obtained to characterize a rising and/or falling pattern (Fig. e29-5).[9,44] The peak troponin concentration marks the point at which ongoing necrosis has ceased and its magnitude can provide a crude estimate of infarct size. Following an MI, elevations in troponin may persist for up to 1 to 2 weeks, particularly in patients with renal dysfunction. Cardiac troponin also has prognostic value following an MI and can be used to risk-stratify patients as well as select an appropriate management approach.[45]

FIGURE e29-5

Serum-time profiles of cardiac biomarkers following myocardial injury. (*A*), myoglobin following acute myocardial infarction (AMI); (*B*), cardiac troponin following AMI; (*C*), creatine kinase–myocardial band (CK-MB) following AMI; (*D*), troponin following unstable angina. *(Reproduced, with permission, from Wu AH, Apple FS, Gibler WB, et al. National Academy of Clinical Biochemistry Standards of Laboratory Practice: Recommendations for the use of cardiac markers in coronary artery diseases. Clin Chem. 1999;45(7):1104-1121.)*

Serum elevations of cardiac troponin may also occur in other cardiovascular disorders, such as tachyarrhythmias and ADHF, as well as several noncardiac conditions (eg, sepsis), although elevations are typically lower. Consequently, its use to establish an MI diagnosis must be placed in context with other findings suggestive of ischemia (eg, symptoms, ECG changes).

Creatine Kinase–Myocardial Band

Creatine kinase–myocardial band (CK-MB) is another biomarker released after myocardial cell death, but substantially greater injury is required to produce detectable concentrations compared to cardiac troponin.[9] Moreover, CK-MB is also present in skeletal muscle and can be released after other types of muscular injury (eg, rhabdomyolysis). For these reasons, it is not preferred in the diagnostic evaluation of MI, although it can be helpful for characterizing the extent of the injury and may be detectable prior to troponin in patients with recent-onset symptoms.[9] Given its short serum half-life, a new rise in CK-MB may be used to distinguish a new infarction in patients with persistently elevated cardiac troponin following an initial ischemic event.

B-Type Natriuretic Peptide

⑥ B-type natriuretic peptide (brain natriuretic peptide; BNP) and its biologically inactive precursor N-terminal pro-BNP (NT-proBNP) are released from ventricular myocytes in response to stretch-related injury, most commonly due to volume overload. The natriuretic peptide system serves as a counter-regulatory response to the renin-angiotensin-aldosterone system, which is commonly activated in patients with HF. Natriuretic peptide concentrations are thus helpful tools in the diagnosis and evaluation of patients with both chronic and ADHF.

Serum BNP and NT-proBNP concentrations are primarily used to support the diagnosis of HF (ie, in concert with other clinical findings), or exclude HF in the differential diagnosis of patients presenting with dyspnea.[46–48] Elevations in serum BNP and NT-proBNP concentrations also portend HF severity as well as long-term morbidity and mortality.[48,49] Consequently, a measurement of baseline natriuretic peptides is recommended in patients admitted with ADHF.[46] An emerging indication for natriuretic peptide concentrations is to determine the prognosis in patients being discharged following ADHF.[46] Finally, an area of ongoing research is the use of serum BNP and NT-proBNP concentrations as a screening tool in patients at risk for developing HF.[50]

Either BNP or NT-proBNP concentrations may be used but their thresholds are different (Table e29-6).[46] Several factors influence natriuretic peptide concentrations, thus clinical interpretation must account for age, gender, and body weight. Normal concentrations are higher in patients of advanced age and female gender and lower in patients who are overweight or obese. Because BNP and, especially, NT-proBNP undergo renal elimination, concentrations are also higher in patients with renal dysfunction. The use of neprilysin inhibitors (eg, sacubitril) must also be taken into consideration, as they may increase BNP but not NT-proBNP concentrations, and may reduce NT-proBNP concentrations over time.[46,51,52]

As with other biomarkers, elevations in BNP and NT-proBNP may also be present in related cardiovascular disorders, such as acute coronary syndromes, asymptomatic left ventricular dysfunction, and PE, as well as in several noncardiac conditions (eg, sepsis).

Inflammatory Mediators

Inflammation plays a pathologic role in several cardiovascular disorders, which has led to research involving the diagnostic and/or prognostic role of several inflammatory mediators. One of the biomarkers for which the most evidence exists is high-sensitivity C-reactive protein (hs-CRP), an acute phase reactant released by the liver in response to inflammation. At present, hs-CRP is regarded as a risk-enhancing factor and is, therefore, most useful for making decisions regarding treatment in patients without clinical ASCVD who are at uncertain risk for cardiovascular events in the future.[3,53]

Biomarkers of Related Metabolic Disorders

The risk of ASCVD increases with the presence and/or severity of certain chronic metabolic conditions, including dyslipidemia and diabetes mellitus. Consequently, biomarkers used in the management of these conditions are important for assessing the patient with or at risk for ASCVD. For patients without clinical ASCVD, screening for traditional risk factors such as dyslipidemia and diabetes mellitus should be performed every 4 to 6 years beginning at age 20; additionally, they should be used as part of the determination of estimated 10-year ASCVD risk every 4 to 6 years beginning at age 40.[54]

Elevations in total cholesterol, triglycerides, and low-density lipoprotein (LDL) concentrations, as well as low concentrations of high-density lipoprotein (HDL) all confer an increased risk of ASCVD. Total cholesterol, LDL, and HDL concentrations are used in the Pooled Cohort equations to determine 10-year ASCVD risk, and LDL concentrations are also used to assess response in patients who meet eligibility criteria for HMG-CoA reductase inhibitor (ie, statin) therapy.[3,53] Apoprotein B and lipoprotein (a) are risk-enhancing factors for ASCVD (Table e29-2) that can also be assessed to inform shared decision making in patients with lower levels of ASCVD risk.[3] The use of specific LDL targets in ASCVD remains controversial and readers are referred to Chapter 32, "Dyslipidemia," for further discussion. Reference ranges for serum lipid concentrations are provided in Table e29-6.

The presence of diabetes mellitus also increases ASCVD risk, and cardiovascular events remain the most common cause of death in patients with the disorder. In general, a hemoglobin A1c <7% (0.07; 53 mmol/mol) is recommended in nonpregnant adults but different goals may be selected in individual patients based on risks and benefits (refer to Chapter 94, "Diabetes Mellitus," for details).[55]

Miscellaneous Laboratory Tests

Several comorbid conditions can cause *de novo* cardiovascular disorders or worsen existing disease. As a result, screening patients for alterations in biomarkers related to these conditions is often part of the routine evaluation of CVD. These may include measurements of thyroid hormones to evaluate for hypo- or hyperthyroidism; complete blood cell counts and markers of iron hemostasis to evaluate for anemia and/or iron regulation disorders, and tests for indicating the presence of human immunodeficiency virus (HIV).

Finally, since the heart is responsible for the circulation of blood to organs and tissues throughout the body, biomarkers of end-organ function may be used as surrogate measures of global cardiac function. Examples routinely used in practice include biomarkers of hepatic injury and function (eg, aspartate aminotransferase, alanine aminotransferase) and renal function (eg, serum creatinine, blood urea nitrogen).

ASSESSING ORGAN FUNCTION

Although considerable information regarding the health of the cardiovascular system can be gleaned from a comprehensive patient interview and targeted physical examination, these tools are occasionally inadequate for assessing the patient with or at risk for CVD. Further diagnostic testing is often required to establish a diagnosis, assess risk, and guide the selection of therapy. The following section provides an overview of some of the common diagnostic and evaluative modalities in cardiovascular medicine.

Electrocardiography

⑦ The ECG is the oldest diagnostic tool used in contemporary practice, and it remains a critical step in the evaluation of a wide range of clinical presentations, including chest pain or discomfort, palpitations, syncope, dizziness, and signs and symptoms of new-onset heart failure. The ECG provides a real-time map of electrical activity across the heart. As with other muscles in the body, the end result of these electrical impulses is a muscular contraction. Therefore, prior to learning the fundamentals of ECG interpretation, a basic framework of how electrical impulses in the heart trigger a muscular contraction is required.

Electrical activation in the heart begins within the right atrium, in the sinoatrial (SA) node (Fig. e29-6). The impulse generated by the SA node is then transmitted as a wave of depolarization across the atria and into the atrioventricular (AV) node. From the AV node, conduction flows through the right and left bundle branches, and finally into the His-Purkinje system, where it is transmitted to the ventricular myocardium. Electrical stimulation of cardiac myocytes triggers the entry of calcium into the cell, which leads to further release of calcium from within the cell, culminating in a muscle contraction. Following contraction, myocytes repolarize in preparation for the next impulse.

FIGURE e29-6

Electrical system of the heart. An electrical impulse begins at the sinoatrial node in the right atrium. Depolarization proceeds to the atrioventricular node. Finally, conduction proceeds down the left and right bundle branches, and then into the Purkinje fibers. *(Reproduced, with permission, from Barrett KE, Barman SM, Brooks HL, Yuan JJ, eds. Ganong's Review of Medical Physiology. 26th ed. New York, NY: McGraw Hill; 2019.)*

Since the heart is a three-dimensional structure, the wave of electrical depolarization does not travel in a straight line. By placing pairs of positively and negatively charged electrodes called leads at different locations across the chest, a comprehensive map of depolarization and repolarization can be produced. A standard ECG consists of 12 leads (Fig. e29-7). Six leads are placed across the chest wall and are named V_1 to V_6 (ie, the precordial or chest leads). The remaining six leads (ie, limb leads) are formed by pairs of electrodes on each arm and leg (or more commonly, on each shoulder and each side of the abdomen in the direction of the lower limbs), which monitor the signal on a frontal plane on the chest. Leads I, II, and III monitor the electrical vectors between the right arm and left arm, right arm and left leg, and left arm and left leg, respectively. Leads aVF, aVL, and aVR (ie, the augmented limb leads) monitor electrical vectors from an imaginary point in the middle of the abdomen to the left leg, left arm, and right arm, respectively.

FIGURE e29-7

Electrocardiogram lead placements. The positions of the unipolar lead placements (V_1-V_6) are shown. Bipolar leads are also placed on both arms and both legs to obtain tracings for leads I, II, and III, and aVL, aVF, and aVR. *(Reproduced, with permission, from Barrett KE, Barman SM, Brooks HL, Yuan JJ, eds. Ganong's Review of Medical Physiology. 26th ed. New York, NY: McGraw Hill; 2019.)*

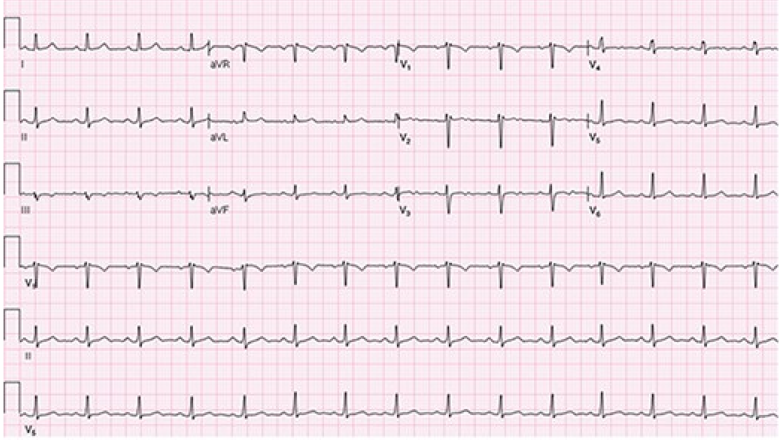
As electrical activity approaches the positive electrode of each lead (for bipolar leads) or the lead itself (for unipolar leads), a positive deflection is recorded. Current moving away from an electrode produces a negative deflection. Electrical signals are recorded from several leads simultaneously over the course of a few seconds, and these are displayed on an ECG (Fig. e29-8). The bottom three tracings of the ECG are often referred to as the *rhythm strip*, as they track the same leads over an entire tracing, facilitating rhythm interpretation. Because no two leads are in the same area, each displays a slightly different electrical signal. Combinations of leads can thus be used to detect a variety of disorders beyond arrhythmias, including the presence of myocardial ischemia and pathologic changes in heart structure, such as chamber enlargement or hypertrophy.

FIGURE e29-8

A normal 12-lead electrocardiogram (ECG). The ECG plots electrical activity on the Y-axis against time on the X-axis. Each lead records for a few seconds and then switches, with the exception of the bottom three, which do not change. These latter three leads constitute the *rhythm strip*, as they permit a more comprehensive assessment of cardiac rhythm.



Source: Joseph T. DiPiro, Gary C. Yee, L. Michael Posey, Stuart T. Haines, Thomas D. Nolin, Vicki L. Ellingrod: *DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e*

The distinguishing features of a normal ECG are shown in Fig. e29-9. The X-axis of the ECG reflects time, and each large box on the ECG graph paper represents 0.2 seconds. The Y-axis reflects the magnitude of the electrical signal in each lead, described in terms of millimeters of deflection above or below the isoelectric baseline. The P wave represents atrial depolarization at the beginning of atrial systole. The PR interval is an isoelectric line from the end of the P wave to the onset of the QRS complex and reflects slowed conduction through the AV node and the delay between atrial and ventricular depolarization. The QRS complex reflects ventricular depolarization and the onset of ventricular systole. The QT interval reflects the delay in ventricular repolarization and the duration of the action potential. Finally, the ST segment and T wave occur during ventricular repolarization at the beginning of ventricular diastole. Normal ranges exist for the amplitude and timing of each wave and segment.

FIGURE e29-9

Terminology used to describe the distinguishing features of a normal ECG. *(Reproduced, with permission, from Barrett KE, Barman SM, Brooks HL, Yuan JX-Y. Ganong's Review of Medical Physiology Examination and Board Review. 26th ed. New York, NY: McGraw Hill; 2019.)*

Interpreting an ECG requires a systematic approach. No "one-size-fits-all" algorithm exists, and most individuals apply the technique of their mentors or training institution. Once a method is selected, clinicians are encouraged to use it consistently. A common approach to ECG interpretation is described in Table e29-7. Rhythm identification is often the most challenging aspect of electrocardiography, and complex arrhythmias may be difficult for even the most experienced cardiologists to interpret. The axis reflects the overall net depolarization vector in the frontal plane (gathered from the limb leads), and certain conduction disorders or cardiovascular conditions may shift this axis. Following identification of the axis, the P wave and QRS amplitude are assessed, as prominent voltage may suggest chamber enlargement or hypertrophy. The QRS complex must be carefully inspected for Q waves (an initial downward deflection in the QRS complex), which may be a sign of prior MI. Next, the ST segments and T waves are inspected. In the appropriate context, ST segment depressions may reflect myocardial ischemia, and ST segment elevations may be seen with myocardial injury, although neither of these changes is specific and should therefore be evaluated in context with other clinical information (eg, symptoms). Finally, the intervals are assessed, as abnormalities may reflect electrolyte disorders.

TABLE e29-7

Approach to Electrocardiogram Interpretation

1. Identify atrial and ventricular rates.
2. Determine rhythm.
3. Determine axis.
4. Assess P and QRS amplitude/duration.
5. Review ST segment and T wave.
6. Calculate QT/QTc interval.

Another important aspect of ECG interpretation is determining the duration of the QT interval, as prolongation increases the risk of polymorphic ventricular tachycardia and sudden cardiac death.[56] The QT interval is measured from the beginning of the QRS complex to the end of the T wave and represents the time required for ventricular depolarization and repolarization. The QT interval varies based on heart rate, and can be corrected according to Bazett's formula as follows:

$$\mathrm{QT_{corrected}} = \frac{\mathrm{QT\ interval}}{\sqrt{\mathrm{RR\ interval}}}$$ QTcorrected=QT intervalRR interval

A normal corrected QT (QTc) interval is <450 msec for men and <460 msec for women.[57] Electrolyte abnormalities (eg, hypokalemia) can affect the QT interval, along with ischemia, commonly prescribed medications (eg, atypical antipsychotics, azole antifungals, select antiarrhythmics), and inherited membrane channelopathies. Because the QT interval is comprised of the QRS complex, ST segment, and the T wave, conditions associated with a widened QRS (eg, bundle branch block, ventricular pacing) will also prolong the QT interval. In these scenarios, the standard QTc reference intervals do not apply.

One of the most common reasons for obtaining an ECG is in the evaluation of palpitations, which may occur intermittently and not at a time when they can be evaluated by a healthcare professional. If a determination of heart rhythm is all that is required, a 12-lead ECG may not be necessary and instead, ambulatory monitoring may be performed using a portable ECG device known as a Holter monitor. Several ECG leads are placed on the patient's chest, and these are attached to a small recorder. All heartbeats are recorded over a period of time (typically 24-48 hours), and the patient keeps a record of any symptoms that emerge. If symptoms occur and correlate with the presence of an arrhythmia on the monitor, a diagnosis may be made. A Holter monitor will also provide information regarding the minimum, maximum, and average heart rates; the number of premature atrial and ventricular beats; and any ST segment changes.

For symptoms that occur very infrequently, an event monitor may be used. An event monitor is similar to a Holter monitor except that the device may be worn for 14 to 28 days. Unlike Holter monitors, event monitors do not record and store every heartbeat. Instead, when patients experience symptoms, they trigger the device with a button, prompting it to record and store several minutes of heart rate and rhythm data. For even less frequent episodes (ie, those occurring less than once a month) in patients with severe symptoms (eg, syncope), an implantable monitor may be surgically placed under the skin, and data can be recorded for many months and transmitted remotely. Portable and wearable devices, such as the Apple Watch (Apple Inc.; Cupertino, CA) have been developed with powerful rhythm monitoring capacities; these devices can detect infrequent arrhythmias, such as paroxysmal atrial fibrillation,[58] and can be paired with a mobile device to store and transmit rhythm strips.

Stress Testing

A resting ECG may be normal in patients with CAD, as blood flow may be adequate for meeting the heart's metabolic needs even in the face of significant obstructive lesions.[59] However, physical exertion produces an increase in heart rate, myocardial contractility, and BP, leading to increased myocardial oxygen demand.[60] In the presence of a fixed coronary stenosis, oxygen delivery will be unable to keep up with demand, and myocardial ischemia may occur, manifesting as chest pain or abnormalities on ECG.

8 Based on these principles, stress testing is a common modality for detecting CAD in patients with anginal symptoms in the absence of an MI. If obstructive CAD is detected, patients may benefit from risk factor reduction, pharmacologic therapy, and potentially coronary angiography and revascularization. Although chest pain is the most common reason for stress testing, other established indications are listed in Table e29-8. Stress testing is not routinely recommended as a screening tool for CAD in asymptomatic patients.

TABLE e29-8

Common Indications for Stress Testing

- Chest pain suggestive of angina
- Risk assessment in patients with unstable angina or non-ST segment acute coronary syndrome
- Preoperative risk assessment in patients undergoing noncardiac surgery
- Assessment of severity in valvular heart disease
- Determining role for coronary revascularization in left ventricular dysfunction
- Clinical significance of arrhythmias or bradycardias

In the United States, most stress tests are performed on a treadmill rather than a bicycle. Although patients may be accustomed to walking or jogging on a treadmill, stress testing differs from a standard exercise regimen. The most common treadmill protocol is the Bruce protocol, which begins at a speed of 1.7 mph (2.7 km/h) and an incline of 10%. The speed then increases by 0.8 mph (1.3 km/h) and the grade increases by 2% every 3 minutes for a total of 21 minutes.[61] During the test, the ECG is monitored continuously, and BP is measured every 3 minutes. Patients are also routinely asked about chest pain symptoms. Most stress tests are symptom-limited, that is, patients exercise until they develop dyspnea that limits further activity. Other indications for early termination of the test include the development of arrhythmias or drastic changes in BP. In properly selected candidates under appropriate supervision, ECG stress testing is safe, with serious complications (eg, ventricular arrhythmias, MI) occurring at a rate of only one event per 10,000 studies.[62]

Patients must achieve 85% of the age-predicted maximum heart rate for a stress test to be diagnostic.[63] If patients cannot achieve this threshold despite maximal exercise, the study is considered “nondiagnostic,” even if no ECG abnormalities are observed. As a result, the presence of CAD cannot be definitively excluded, and alternative testing should be considered.

The development of chest pain, especially if accompanied by ECG abnormalities, is highly specific for CAD.[64] A positive stress test is defined as a change on the ECG of 1 mm of down-sloping or horizontal ST segment depressions in two contiguous leads persisting 80 msec after the QRS complex.[65] ST segment depressions can occur during exercise or in the recovery period after the test. If ST segment elevation occurs in a patient without baseline Q waves, profound myocardial ischemia is likely present, and the study should be terminated immediately so that urgent cardiac catheterization may be performed.

When certain ECG abnormalities are present at baseline, such as left ventricular hypertrophy with prominent repolarization abnormalities, the development of ST segment depression loses both sensitivity and specificity.[65] Additionally, the presence of a left bundle branch block renders the ST segments uninterpretable, and treadmill testing should not be performed; instead, pharmacologic vasodilator testing should be considered (discussed later).

Stress testing also suffers from the limitations common to all diagnostic studies, in that there may be both false positive and false negative results, and the likelihood of a positive test is dependent on the pretest probability of disease. Consequently, stress testing should not be the sole factor in determining whether further testing (eg, coronary angiography) should be performed. Instead, multiple data points should be considered, including traditional ASCVD risk factors and the nature of the patient’s symptoms.

For patients who are unable to exercise (eg, orthopedic limitations, other factors that may limit ambulation) or who cannot achieve the target heart rate, pharmacologic stress testing may be performed instead. In a pharmacologic stress test, one of two mechanisms is employed: administration of an agent that increases myocardial oxygen demand and results in ischemia, or administration of an agent that dilates the coronary arteries, resulting in relative regional perfusion abnormalities. Since pharmacologic stress testing is always performed in conjunction with additional imaging studies such as echocardiography or radionuclide imaging, this modality will be discussed in further detail in the section on nuclear cardiology later in this chapter.

Echocardiography

⑨ Aside from the ECG, echocardiography is the most common modality for assessing cardiac function and the presence of CVD. Echocardiography is a noninvasive test involving the emission of ultrasound waves, which travel through tissue and are reflected back to a transducer probe, where they are processed to construct images of the heart and related structures. In early forms of echocardiography, only one-dimensional (m-mode) ultrasound was available. However, as probe technology improved, two-dimensional echocardiography was developed (Fig. e29-10). Although most devices are now capable of generating three-dimensional echocardiographs, two-dimensional imaging can be rapidly performed and is accurate and effective at answering most clinical questions.

Echocardiographic images are broadly classified according to where the probe is placed during the procedure. During a transthoracic echocardiogram (TTE), the transducer probe is placed on several locations on the chest and upper abdomen. A TTE provides information on the chambers, valves, and contractile function of the heart. Consequently, TTE is the imaging modality of choice for the assessment of valvular heart disease, left and right ventricular function, and pericardial effusions. It is also a cornerstone in the evaluation of HF, as left ventricular ejection fraction (LVEF) is often critical in therapeutic decision making.

An application of ultrasound is Doppler echocardiography, in which the directional flow and velocity of red blood cells can be visualized. Color Doppler images provide a qualitative assessment of turbulent blood flow through the heart valves, which can be subsequently classified as either regurgitation or stenosis. A continuous-wave Doppler provides a quantitative measurement of blood velocity (Fig. e29-11), which can then be used to calculate the pressure gradients across the valves and valve areas, and estimate pulmonary artery pressures. A more recent application of Doppler imaging is measuring myocardial tissue velocities, which can be useful in assessing diastolic function and determining prognosis in chronic HF.

Echocardiography can also be used to detect intracardiac shunting. Color Doppler interrogation of the interatrial septum may detect left to right shunts, most commonly as a result of atrial septal defects. Additionally, in a procedure known as a bubble study, saline can be agitated to create microbubbles, which are then injected into an intravenous line. In a structurally normal heart, these bubbles will appear in the right ventricle but are subsequently absorbed in the lungs. However, bubbles that emerge on the left side of the heart suggest the presence of a right to left shunt, such as a patent foramen ovale (PFO).

Advantages of TTE are that it is highly portable, reproducible, and images can be obtained in even the most critically ill patients in the intensive care unit or operating room. Additionally, ultrasound waves do not use ionizing radiation, and intravenous access is not required for most procedures. However, occasionally a TTE is unable to provide satisfactory imaging. For example, in trauma or postoperative patients, the presence of lines and tubes as well as chest wall abnormalities may limit acoustic windows. Additionally, ultrasound waves are reflected by air and degrade as they travel through tissue, which may result in poorer image quality in obese patients. Contrast echocardiography, in which gas-filled microbubbles are injected intravenously, can improve the assessment of LV size and function in patients with poor imaging windows.[66] Finally, because of the orientation of the heart within the thoracic cavity, some structures located toward the posterior aspect of the heart are poorly visualized with a TTE. Similarly, TTE may not provide the image clarity necessary to evaluate subtle abnormalities, such as valvular vegetations. Fortunately, if information regarding these latter structures is needed, a transesophageal echocardiogram (TEE) may be performed.

During a TEE, the transducer probe is advanced through the mouth and into the patient’s esophagus where ultrasound waves are transmitted through the posterior aspect of the heart. A TEE is commonly used to evaluate for the presence of aortic dissections, left atrial appendage thrombus prior to cardioversion, and valvular vegetations in patients with bacteremia or suspected endocarditis. Because of the close proximity of these structures to the esophagus (especially the mitral and aortic valves), TEE images are of higher quality than TTE. Consequently, TEE is used extensively in the operating room to ensure the proper functioning of newly implanted heart valves and overall heart function in patients undergoing CABG surgery.

Although a TEE is generally considered to be a safe procedure, it is invasive and therefore carries a small inherent risk.[67] Trauma to the esophagus and the vocal cords are rare but known complications of TEE. Contraindications include esophageal pathology that may limit the advancement of the probe, untreated esophageal varices, and oropharyngeal or cervical spine conditions that limit neck extension and flexion. Conscious sedation is used for procedural comfort and safety, and appropriate cardiac and respiratory monitoring by specialized personnel are required.

Echocardiography can also be used in conjunction with ECG stress testing to improve its sensitivity and specificity, as ischemia-related changes in systolic or diastolic function may be detected prior to ECG changes or ischemic symptoms. Stress echocardiography can be performed with exercise using a treadmill or bicycle, or pharmacologically, most commonly with dobutamine. Dobutamine is a beta-receptor agonist, which induces physiologic changes similar to exercise (eg, increased myocardial contractility and heart rate), leading to increased myocardial oxygen demand. At peak exercise (or peak dobutamine infusion), echocardiogram images are obtained and compared to baseline images. Myocardium that is well-perfused will become hyperkinetic with stress, whereas ischemic segments may appear hypokinetic compared to baseline, and relatively hypokinetic compared to areas receiving adequate blood supply.

Cardiac Catheterization

Cardiac catheterization (or heart catheterization) is a procedure in which a catheter is inserted percutaneously into a large blood vessel and advanced to the heart, where it is used to obtain diagnostic or evaluative information. Therapeutic interventions may also be performed. Cardiac catheterization can be broadly classified as being left-sided (left heart catheterization or LHC) or right-sided (right heart catheterization or RHC), depending on whether the catheter is inserted into an artery (LHC) or vein (RHC). The selection of LHC versus RHC depends on the information desired. The common indications for each are listed in Table e29-9.[68]

TABLE e29-9

Common Indications for Cardiac Catheterization

Left Heart Catheterization	Right Heart Catheterization
• Acute coronary syndromes • Cardiogenic shock • Cardiomyopathy, with or without symptoms of heart failure • Coronary artery disease, especially if symptomatic and/or high-risk features are present (eg, new systolic dysfunction) • Pericardial tamponade • Valvular disease, as a preoperative evaluation prior to surgery or with indeterminate severity • Ventricular arrhythmias, including resuscitated cardiac arrest	• Acute decompensated heart failure, with indeterminate volume status, change in clinical condition, and/or to guide therapy (eg, inotropes) • Pulmonary hypertension • Surveillance endomyocardial biopsy after heart transplantation • Shock

Data from Reference 68.

Bleeding from the access site is the most common complication of cardiac catheterization and thus coagulopathies and other bleeding diatheses should be corrected prior to the procedure. If radiocontrast dye is to be used as in the case of a LHC, the benefits of cardiac catheterization must be weighed against the risk of worsening preexisting renal dysfunction. Providing adequate hydration and limiting the volume of contrast dye used during the procedure may ameliorate the risk of renal injury.[9] Alternative strategies, such as the administration of oral N-acetylcysteine, are not effective and therefore not recommended.[69] With the exception of severe anaphylactic reactions, patients with allergies to contrast dye can often undergo cardiac catheterization safely if adequately premedicated prior to the procedure. Regimens for allergy prophylaxis generally consist of a corticosteroid and histamine-receptor blocker (eg, diphenhydramine). The need to provide prophylaxis in patients with shellfish or seafood allergies is a common misconception and is not recommended.[69]

Other relative contraindications to cardiac catheterization include hemodynamic instability, uncontrolled hypertension, intractable arrhythmias, severe electrolyte derangements, and systemic infections. Because of the invasive nature of the procedure and the risk of complications, cardiac catheterization is typically performed in a procedural unit by a specialized team and may not be available at smaller medical facilities.

Left Heart Catheterization

⑩ During LHC, a catheter is inserted percutaneously through an incision in a large peripheral artery, such as the femoral or radial artery, and advanced in a retrograde fashion to the cardiac structure of interest. Access via the radial artery is becoming more common because of lower complication rates, faster recovery times, and improved patient satisfaction.[70]

The most common indication for LHC is coronary angiography, a procedure in which fluoroscopy (real-time x-ray) is used to diagnose or evaluate ASCVD. During the procedure, a catheter is advanced into the coronary arteries, where a contrast dye is injected to visualize the coronary anatomy and detect occlusion of blood flow (Fig. e29-12). Fluoroscopy produces two-dimensional images; given the three-dimensional nature of coronary anatomy and blood flow, multiple projections are required to accurately characterize and grade coronary lesions. Areas of stenosis are considered to be significant when the diameter of the arterial lumen has narrowed by ≥70% (≥50% for the left main artery).[69]

A limitation of angiography is that it does not provide information regarding the physiologic implications of a coronary lesion, such as whether the degree of stenosis present results in myocardial ischemia. In patients with stable coronary disease, revascularization of lesions because they appear stenotic to the operator does not improve outcomes.[71] For indeterminate lesions (50%-70% stenosis), fractional flow reserve (FFR) may indicate scenarios in which an intervention may be deferred. During FFR, a coronary vasodilator is administered, and the pressure difference across the area of stenosis is used to calculate flow. An FFR value of ≤0.80 (ie, ≥20% reduction in flow) is generally considered hemodynamically significant and thus warrants revascularization.[69]

Another limitation of angiography is that it does not provide information on the arterial wall, nor details regarding the morphology of a coronary lesion (eg, plaque volume, area, cross-sectional area). In cases where this information may alter treatment, a specialized catheter can be used to perform intravascular ultrasound (IVUS). Like FFR, IVUS may be used to guide decision making in patients with indeterminate lesions, but it is less commonly used for this purpose due to the added complexity and expense of the procedure. Instead, IVUS is primarily reserved for the assessment of cardiac allograft vasculopathy (CAV), a special type of CAD found in heart transplant recipients, characterized by diffuse narrowing of the vessel lumen rather than the development of discrete lesions.[69]

If a significant coronary occlusion or severe stenosis is detected, a percutaneous coronary intervention (PCI) may be performed to restore blood flow (see Chapter 33, “Stable Ischemic Heart Disease” for more detailed explanation of PCI). Restoration of blood flow following PCI can be graded according to Thrombolysis in Myocardial Infarction (TIMI) Grade Flow on a scale of 0 to 3, where 0 represents no flow and 3 represents normal flow. Blood flow receiving a TIMI 1 score represents a partial restoration of flow but an incomplete filling of distal vessels, whereas a TIMI 2 score represents delayed flow but a complete filling of distal vessels. In instances where a patient would benefit from CABG surgery over PCI, LHC may be terminated once the anatomy has been characterized via angiography. The films obtained during LHC are then used by cardiac surgeons to determine the optimal grafting strategy for restoring blood flow.

Right Heart Catheterization

⑪ During RHC, a catheter is inserted percutaneously through an incision in a large vein, such as the IJ, femoral, or brachial vein, and advanced to the right side of the heart. Several diagnostic and therapeutic procedures can be performed with RHC, the most common of which is an assessment of cardiac hemodynamics. Reference ranges for common hemodynamic values are provided in Table e29-10. When hemodynamic values are needed in an urgent scenario, RHC can be performed at the bedside; otherwise, it is more commonly performed in the cardiac catheterization lab with fluoroscopic guidance.

TABLE e29-10

Reference Ranges for Common Hemodynamic Values[a]

Hemodynamic Parameter	Reference Range
Heart rate (HR)	60-110 bpm
Cardiac output (CO)	4-6 L/min (0.07-0.1 L/s)
Cardiac index (CI)	2.8-4.2 L/min/m^2 (0.047-0.07 L/s/m^2)
Right atrial pressure (RAP)[b]	2-6 mm Hg
Right ventricular pressure (systolic/diastolic)	15-30 / 8-15 mm Hg
Mean pulmonary arterial pressure (mPAP)	10-20 mm Hg
Pulmonary arterial pressure (PAP, systolic/diastolic)	15-30 / 5-15 mm Hg
Pulmonary vascular resistance (PVR)	150-250 dynes·s/cm^5 (15-25 MPa·s/m^3)
Pulmonary capillary wedge pressure (PCWP)	6-12 mm Hg
Left atrial pressure (LAP)	4-12 mm Hg
Left ventricular pressure (systolic/diastolic)	100-140 / 4-12 mm Hg
Mean arterial pressure (MAP)	70-100 mm Hg
Systemic arterial pressure (systolic/diastolic)	100-120 / 60-80 mm Hg
Systemic vascular resistance (SVR)	800-1,200 dynes·s/cm^5 (80-120 MPa·s/m^3)

[a] The values presented in this table represent reference ranges, and may differ slightly from other resources; additionally, the “normal” value in an individual patient may vary according to clinical context (eg, a resting heart rate of 55 may be normal in a professional athlete).

[b] May be reported as central venous pressure (CVP).

Although the routine use of invasive hemodynamic monitoring in patients with ADHF does not improve outcomes over clinical assessment alone, subsets of patients may still benefit from the information it provides, such as those patients whose volume or perfusion status remains unclear despite a thorough clinical evaluation or those whose status does not improve despite appropriate therapy (see Chapter 37, “Acute Decompensated Heart Failure”).[15,68,72] An assessment of cardiac hemodynamics is also essential to determining patient eligibility for advanced therapies, such as mechanical circulatory support and cardiac transplantation, as well as in the diagnosis and evaluation of pulmonary hypertension.[68,73]

During an assessment of cardiac hemodynamics, a special balloon-tipped catheter known as a pulmonary artery (PA) catheter or Swan-Ganz catheter is advanced through the right atrium, right ventricle, and into a small branch of the PA, where pressures in each of these areas are measured (Fig. e29-13). The catheter can also be used to administer fluids and medications, and a thermistor near the distal end of the catheter measures changes in temperature. The catheter may be inserted to obtain a single set of measurements and then removed, or it may be sutured in at the access site and left inside the patient to guide titration of vasoactive medications.

After being advanced into a small branch of the PA, the balloon at the end of the catheter can be inflated to transiently occlude the artery, producing what is known as the pulmonary capillary wedge pressure (PCWP) or the pulmonary artery occlusion pressure. In the absence of significant pulmonary vein stenosis or mitral valve disease, the PCWP provides an estimate of left atrial pressure, which is approximately equal to the left ventricular end-diastolic pressure (LVEDP). The LVEDP is a surrogate measure of cardiac preload and can be used as an assessment of a patient's overall volume status.

Other key hemodynamic parameters that can be obtained during RHC are cardiac output (CO) and systemic vascular resistance (SVR). In practice, the CO is often normalized for body surface area and reported as the cardiac index (CI). Estimates of CO can be made using either the Fick or thermodilution method. According to the Fick principle, CO can be calculated by dividing total oxygen consumption within a unit of time by the arteriovenous oxygen difference. Although the Fick method has historically been considered the gold standard for determining CO, prior methods involved direct measurements of oxygen consumption requiring a metabolic cart. Since these are rarely used in contemporary practice in the cardiac catheterization lab, oxygen consumption is often assumed based on gender and body size, making it less reliable in some patients. For example, the Fick method is less accurate in patients with disorders that affect oxygen diffusion and transport, such as pulmonary disorders or anemia.

An alternative to the Fick equation is the thermodilution method, during which CO can be estimated by measuring a change in blood temperature as it flows between two points. During the thermodilution procedure, a small bolus of cold saline is infused from a proximal port on the PA catheter and the resulting change in blood temperature is measured at the thermistor on the distal end of the catheter. Greater changes in temperature between the two points are indicative of slower blood flow and thus reduced CO. As with the Fick method for determining CO, the thermodilution method is also subject to confounding by coexisting conditions, such as intracardiac shunts or regurgitant blood flow. The thermodilution CO is considered more reliable than the Fick method and should be calculated and reported when possible.

Once known, CO can be combined with the mean arterial pressure (MAP) and central venous pressure (CVP) to calculate SVR, an estimate of the resistance force imparted by the systemic vasculature. Because arterial impedance is often the greatest contributor of resistance against the ejection of blood out of the left ventricle, the SVR is commonly used as a surrogate for cardiac afterload. The use of CO, MAP, and CVP to calculate SVR is depicted in the following equation:

$$\text{SVR (dynes} \cdot \text{sec/cm}^5) = \left(\frac{\text{MAP} - \text{CVP}}{\text{CO}}\right) \times 80$$

SVR (dynes · sec/cm5)=(MAP−CVPCO)×80

Another common use of RHC is in the diagnosis and evaluation of pulmonary hypertension (PH), which is defined as a mean PA pressure >20 mm Hg. If elevated due to excess volume, PA pressures will improve and often normalize following reductions in PCWP. However, if PA pressures remain elevated despite a high-normal PCWP (≤15 mm Hg) and PVR is also elevated (>3 Wood units), a diagnosis of pre-capillary PH can be made.[73] Further evaluation is then required to distinguish among the various types of pre-capillary PH. In patients with PAH, a specific type of pre-capillary PH, RHC may be used to determine eligibility for high-dose calcium channel blocker therapy (termed vasoreactivity testing) as well as to guide the titration of disease-modifying therapies. Readers are referred to Chapter 46, "Pulmonary Artery Hypertension," for a more comprehensive discussion of these topics.

Patients being evaluated for cardiac transplantation must undergo RHC to determine the reversibility of elevated PA pressures. During a "vasodilator challenge," a vasodilating agent such as sodium nitroprusside is administered until PA systolic pressures are ≤50 mm Hg or PVR is ≤3 Wood units (≤240 dynes·s/cm^5 [24 MPa·s/m^3]). Patients unable to achieve these parameters without compromising SBP (<90 mm Hg) are deemed ineligible for cardiac transplantation and may require a left ventricular assist device or pharmacotherapy to treat pulmonary hypertension prior to listing.[74] Recipients of a heart transplant must also undergo routine RHC for the purposes of endomyocardial biopsy, a procedure in which samples of myocardial tissue are obtained from the septal wall of the right ventricle and evaluated for the presence of graft rejection.

Chest Radiography (x-ray)

A chest radiograph or x-ray is a noninvasive imaging test that provides visual information about the heart, lungs, and related structures within the thoracic cavity. Chest x-rays are useful in differentiating acute dyspnea due to cardiogenic versus non-cardiogenic etiologies (eg, pneumonia, acute respiratory distress syndrome, effusion, pneumothorax). A chest x-ray is also recommended as part of the initial evaluation of patients suspected as having new or worsening HF even in the absence of dyspnea, as it can provide important information regarding the size and shape of the heart as well as other disorders that may contribute to HF.[15] The two standard views for a chest x-ray are the posteroanterior (front) and lateral (side) views.

Compared to an echocardiogram, a chest x-ray is not as helpful for visualizing structures within the heart and is therefore most often used to depict its overall size and shape. Relative heart size can be approximated in the posteroanterior view by the cardiothoracic ratio (CTR), which is the maximal horizontal diameter of the heart divided by the maximal horizontal diameter of the thorax. A CTR <0.5 is generally considered normal, whereas higher values indicate cardiac enlargement (ie, cardiomegaly). An elevated CTR may also be present in the setting of a pericardial effusion. Dilation of specific heart chambers can also be visualized with chest x-ray. Left ventricular enlargement is visualized as inferior and lateral displacement of the cardiac apex on posteroanterior view, whereas right ventricular enlargement is most optimally viewed as an intrusion into the retrosternal space.

Visualization of the lung fields is also important in the evaluation and management of pulmonary edema. Pulmonary edema due to an underlying cardiogenic etiology is commonly evidenced by bilateral opacities (sometimes referred to as a "bat wing" pattern) (Fig. e29-14). Bilateral pleural effusions are common and cause blunting of the costophrenic angles. Other findings characteristic of pulmonary edema include septal lines (also called Kerley B lines) seen at the bases of the lungs, thickening of the interlobar fissures, and peribronchial cuffing. Serial chest x-rays can be used to assess changes in pulmonary edema over time, complementing other information used in the management of dyspnea.

SPECIAL PROCEDURES

Nuclear Cardiology

⑧ For circumstances in which treadmill ECG testing is inappropriate or does not provide an adequate assessment of CAD, a technique known as radionuclide myocardial perfusion imaging (MPI) can be performed in conjunction with stress testing. In MPI, a cardiac-specific radionuclide tracer is administered intravenously, where it can be taken up by cardiac myocytes. The tracer will not be taken up by ischemic or scarred myocardium due to impaired blood flow, and the resulting pattern can be detected by gamma cameras, which rotate around the patient and construct a three-dimensional model of the heart. The two MPI techniques currently in use are simple photon emission computed tomography (SPECT) and position emission tomography (PET).[75] In contrast with stress echocardiography, ionizing radiation is emitted with either MPI technique; although the risks conferred by an individual test are small, they accumulate with repeated studies and may result in significant radiation exposure over a lifetime.

In a standard nuclear stress protocol, patients receive an intravenous injection of the radionuclide tracer at rest. If defects are present at rest, this often suggests the presence of scar (ie, prior MI) or severely ischemic (hibernating) myocardium. Patients are then subjected to stress, which may be induced by exercise or the administration of a pharmacologic agent. Exercise protocols are similar to those used in standard treadmill testing. When patients achieve peak stress, the tracer is administered a second time. A computer processes the two sets of images, and by convention, the stress images are displayed above resting images (Fig. e29-15).

In contrast to SPECT imaging, PET scanning protocols can only be performed with a pharmacologic agent.[76,77] Consequently, if information such as functional capacity or exercise tolerance is required, PET should not be ordered. In either technique, pharmacologic stress is commonly induced using an intravenous coronary vasodilator rather than a beta-receptor agonist. Intravenous coronary vasodilators can increase blood flow by up to five times greater than that of resting blood flow. However, in patients with an obstructive coronary lesion, the degree of blood flow during stress will be significantly lower distal to the lesion when compared to healthy, nonobstructed arteries. The resulting differences in flow between ischemic and nonischemic tissue will emerge as different patterns of myocardial tracer uptake, producing perfusion defects on SPECT or PET imaging. Historically, pharmacologic MPI was performed primarily with adenosine. However, regadenoson, the selective adenosine A_{2A} receptor agonist, has been used more frequently over the past decade.[76] Due to their enhanced receptor specificity, adenosine A_{2A} receptor agonists produce fewer adverse effects, such as flushing, chest pain, and dyspnea.[77]

The decision to use PET versus SPECT is largely a function of institutional expertise and availability. Of the two MPI techniques, SPECT has been around for longer, and SPECT cameras are more widely available. However, the PET photon exhibits higher energy and is not degraded as readily by soft tissue, resulting in improved resolution and fewer artifacts in obese patients or in women with large breasts.[75] Additionally, although perfusion tracers (eg, rubidium 82) are used in stress testing, PET tracers capable of assessing myocardial metabolism (radiolabeled glucose) also exist.

An indication for which radiolabeled glucose may be used is to determine whether the cardiac function is likely to recover following coronary revascularization. As described above, a resting perfusion defect may represent either scar or hibernating myocardium. A viability study is used to distinguish between these two physiologic states. Fludeoxyglucose (FDG) is a radioactive glucose analog taken up by viable tissue, and patients with a perfusion/metabolism mismatch (ie, absent perfusion but active metabolism) on PET are considered to have viable, hibernating myocardium, which may recover function following revascularization.

Finally, while PET and SPECT can provide reliable, reproducible, and accurate measurements of LVEF, a more traditional approach to LVEF assessment using radionuclide tracers is ventriculography. The most common technique still used for this purpose is multiple gated blood pool imaging (MUGA). With MUGA, red blood cells are radiolabeled, and changes in the tracer count in the right and left ventricles are measured throughout the cardiac cycle. Historically, MUGA was considered a reliable and reproducible method for producing a quantitative assessment of LVEF and was traditionally used to monitor patients receiving cardiotoxic chemotherapy. Although MUGA is still used, gated SPECT and PET scans are increasingly used for this purpose.

Computed Tomography

⑫ Cardiac computed tomography (CCT) is a noninvasive imaging modality in which a series of x-rays are used to construct a three-dimensional image of the heart (Fig. e29-16). Most modern CCT procedures are performed using multidetector-row computed tomography (MDCT), which permits visualization of the coronary arteries. Consequently, CCT angiography has emerged as a non-invasive alternative to cardiac catheterization for evaluating the presence and severity of CAD when there is no concern for active ischemia.[78] Other indications for CCT include assessments of congenital coronary artery anomalies and mapping the pulmonary vein anatomy in preparation for atrial fibrillation ablation.

The use of CCT angiography over functional tests (eg, stress tests) in patients with suspected or stable CAD remains controversial. Functional tests can detect obstructive CAD but lack the sensitivity to detect atherosclerosis in its earlier stages when it may be more amenable to risk reduction strategies. Despite the long-term risks of nonobstructive disease, CCT angiography does not decrease morbidity and mortality compared to functional tests.[79] Although the noninvasive nature of CCT angiography confers several advantages over cardiac catheterization, it still requires the use of iodinated radiocontrast dye. Consequently, allergic reactions and acute kidney injury can occur with CCT angiography.

Another consideration during CCT is that imaging results can be confounded by motion artifacts. A heart rate of less than 60 to 70 bpm is needed for optimal imaging, and the presence of tachyarrhythmias may preclude CCT in some patients. Agents that slow AV node conduction, such as beta-blockers or nondihydropyridine calcium channel blockers, may be administered to slow heart rate. Patients must also be able to hold their breath for up to 20 seconds during the procedure.

A common use of CCT, especially in patients without established CAD, is to detect the presence of coronary artery calcification (CAC), a finding associated with ASCVD events.[80] Because CAC provides limited incremental value over traditional cardiovascular risk factors, its use is primarily reserved for patients whose risk remains uncertain.[53] CAC is expressed as a score that ranges from 1 to 99 (mild disease) to ≥400 (severe disease). Scores are highly sensitive for the presence of CAD but only moderately specific. Most patients over 50 to 60 years will have some degree of coronary calcification.[81] As a result, CAC results are provided both as a score and an age-adjusted percentile. An advantage of using CAC score over other risk evaluation modalities is that it can be obtained without radiocontrast dye and using a protocol that requires only minimal radiation.

Cardiovascular Magnetic Resonance Imaging

Cardiovascular magnetic resonance imaging (CMR) is a noninvasive imaging test that permits an evaluation of the structure and function of the heart in three dimensions (Fig. e29-17). A major advantage of CMR is that images with high spatial and temporal resolution can be constructed without the use of ionizing radiation or iodinated contrast media.[82] The most common indication for CMR is determining the etiology of HF when an underlying cause remains unclear after initial evaluation (eg, echocardiography, angiography in patients with ischemic symptoms). The use of CMR is particularly useful in the diagnosis of less common causes of nonischemic cardiomyopathy, including inflammation (eg, myocarditis) and infiltrative disorders (eg, cardiac amyloid or sarcoid). In patients with ischemic disease, CMR may identify viable myocardium amenable to revascularization and may be used in combination with pharmacologic stress testing. Late gadolinium enhancement (LGE) is a technique used in many CMR cases to differentiate diseased from normal myocardium, and the pattern of enhancement observed via LGE can indicate the type of injury present (eg, ischemic, infiltrative).

FIGURE e29-15

A normal positron emission tomography scan. The images shown are cross-sections of the short axis (top two rows), vertical long axis (middle two rows), and horizontal long axis (bottom two rows) of the heart. Stress images are on the top, and resting images on the bottom of each pair of rows. The perfusion patterns are similar in both sets of images, consistent with a low likelihood of obstructive coronary artery disease. *(Reproduced, with permission, from Gupta N, Matta EJ, Oldham SA. Cardiothoracic imaging. In: Elsayes KM, Oldham SAA, eds. Introduction to Diagnostic Radiology. New York: McGraw Hill; 2014.)*

FIGURE e29-17

In the top two panels, cardiac magnetic resonance (CMR) imaging showing late gadolinium enhancement in the walls of both the left and right ventricle (indicated by red arrows). Below, a series of images from a positron emission tomography scan show extensive metabolic function. Together these findings are suggestive of active inflammation consistent with a diagnosis of cardiac sarcoidosis. *(Reproduced, with permission, from Gupta N, Matta EJ, Oldham SA. Cardiothoracic imaging. In: Elsayes KM, Oldham SAA, eds. Introduction to Diagnostic Radiology. New York: McGraw Hill; 2014.)*

Historically, CMR has been contraindicated in patients with cardiac implantable electronic devices. However, an increasing number of devices have been deemed magnetic resonance (MR) conditional, meaning they are not known to be hazardous during CMR. Recommendations regarding CMR in patients with MR conditional devices were recently published and many types of non-MR-conditional devices may safely undergo CMR at institutions with sufficient expertise.[83,84] All patients should be screened for the presence of devices with ferromagnetic components prior to CMR and some devices remain contraindicated with CMR (eg, ventricular assist devices). Mechanical heart valves and intracardiac stents can be safely imaged with CMR.

Most of the remaining risks of CMR relate to the use of LGE. As with other types of imaging media, a subset of patients may experience allergic reactions to gadolinium, which range from mild-to-moderate symptoms (eg, itching) to anaphylaxis in rare cases.[82] Another rare complication of gadolinium administration is nephrogenic systemic fibrosis, which may lead to renal failure in patients with preexisting moderate-to-severe kidney disease.

CONCLUSION

Although the technologies available to evaluate patients with or at risk for CVD have grown considerably over the last several decades, patient interview and physical examination continue to play a critical role in its initial detection and assessment. Significant insight into the development and progression of CVD can also be provided by noninvasive tests, such as ECG, echocardiography, and stress testing. More advanced or invasive testing may be required in those with indeterminate findings. Many of these tests are not without risks and this must be carefully weighed against the potential benefits. Moreover, unnecessary testing is one of the major drivers of healthcare costs in the United States and has prompted calls for greater stewardship of healthcare resources.[85] The need for each test should be considered in the context of the patient's overall condition and, most importantly, whether the findings of the test would change patient management or treatment.

ABBREVIATIONS

ABI	ankle-brachial index
ABPM	ambulatory blood pressure monitoring
ADHF	acute decompensated heart failure
ASCVD	atherosclerotic cardiovascular disease
AV	atrioventricular
BNP	brain natriuretic peptide
BP	blood pressure
CABG	coronary artery bypass graft
CAC	coronary artery calcification
CAD	coronary artery disease
CCT	cardiac computed tomography
CMR	cardiovascular magnetic resonance imaging
CVP	central venous pressure
CI	cardiac index
CK-MB	creatine kinase–myocardial band
CO	cardiac output
CVD	cardiovascular disease
CTR	cardiothoracic ratio
DBP	diastolic blood pressure

ECG	electrocardiogram
EP	electrophysiology
FFR	fractional flow reserve
HBPM	home blood pressure monitoring
HDL	high-density lipoprotein
hs-CRP	high-sensitivity C-reactive protein
HF	heart failure
IVUS	intravascular ultrasound
JVP	jugular venous pressure
LGE	late gadolinium enhancement
LHC	left heart catheterization
LDL	low-density lipoprotein
LVEDP	left ventricular end-diastolic pressure
LVEF	left ventricular ejection fraction
MAP	mean arterial pressure
MDCT	multidetector-row computed tomography
MI	myocardial infarction
MPI	myocardial perfusion imaging
MR	magnetic resonance
NT-proBNP	N-terminal pro-brain natriuretic peptide
PA	pulmonary artery
PAD	peripheral arterial disease
PAH	pulmonary arterial hypertension
PCI	percutaneous coronary intervention
PCWP	pulmonary capillary wedge pressure
PET	positron emission tomography

PH	pulmonary hypertension
PMI	point of maximal impulse
PND	paroxysmal nocturnal dyspnea
PVR	pulmonary vascular resistance
RHC	right heart catheterization
SA	sinoatrial
SBP	systolic blood pressure
SOB	shortness of breath
SPECT	simple photo emission computed tomography
SVR	systemic vascular resistance
TBI	toe-brachial index
TEE	transesophageal echocardiogram
TIMI	Thrombolysis in Myocardial Infarction
TTE	transthoracic echocardiogram

SELF-ASSESSMENT QUESTIONS

1. All of the following are traditional risk factors for cardiovascular disease, except:
    - A. Hypertension
    - B. Physical activity
    - C. Total cholesterol
    - D. Chronic kidney disease
2. Which of the following characteristics can be used to differentiate nonischemic from ischemic chest pain?
    - A. Concomitant nausea or epigastric pain
    - B. Relief when sitting up and leaning forward
    - C. Radiation to the neck, jaw, or shoulder
    - D. Improvement with rest
3. All of the following are important steps for obtaining an accurate blood pressure measurement, except:
    - A. Using the arm that gives the lower reading at each visit
    - B. Removing clothing that covers the location of the cuff
    - C. Being seated for at least 5 minutes prior to the reading
    - D. Using a cuff that encircles at least 75% of the arm

The next two questions (Questions 4 and 5) relate to the following vignette:

A 64-year-old man with a history of nonischemic cardiomyopathy presents to clinic with gradually worsening shortness of breath over the past several weeks.

4. When interviewing the patient about his symptoms, which of the following can be used to characterize orthopnea?
    - A. The number of city blocks he can walk before dyspnea occurs
    - B. Whether he is awakened at night by sudden episodes of dyspnea

   C. Whether dyspnea occurs when he walks up a flight of stairs

   D. The number of pillows he requires to sleep comfortably

5. Which of the following physical examination findings would suggest that volume overload is the cause of his symptoms?

   A. An S_2 heart sound on auscultation of the chest

   B. A jugular venous pressure of 8 cm above the sternal notch

   C. Wheezes on auscultation of the lungs

   D. A negative abdominojugular reflux test

6. In the absence of a history of vascular complications, which of the following physical examination findings in isolation is suggestive of peripheral arterial disease warranting further evaluation?

   A. Bilateral lower extremity edema

   B. An ankle-brachial index of 1.2

   C. Presence of a femoral artery bruit

   D. Absence of leg hair bilaterally

7. The following laboratory values were obtained from a patient who was diagnosed with a myocardial infarction (MI) after presenting to the emergency department with chest pain and shortness of breath: cardiac troponin T 3.0 ng/mL (mcg/L), creatinine kinase-myocardial band (CK-MB) 24 ng/mL (mcg/L), and brain natriuretic peptide (BNP) 40 pg/mL (ng/L; 12 pmol/L). Based on these results, which of the following is true?

   A. The CK-MB value is sufficient for making an MI diagnosis.

   B. Obtaining a high-sensitivity C-reactive protein would be helpful for further risk stratification.

   C. It is unlikely that the patient has coexisting heart failure based on the BNP value.

   D. Compared to cardiac troponin T, it will take longer for the CK-MB to return to normal.

8. First-degree atrioventricular (AV) block refers to slowed AV nodal conduction, which can occur with excess doses of beta-blocker therapy. Which of the following components of an electrocardiogram would be most useful for detecting this phenomenon?

   A. PR interval

   B. QRS complex

   C. QT interval

   D. ST segment

9. For which of the following scenarios would a transesophageal echocardiogram (TEE) be preferred over a transthoracic echocardiogram (TTE)?

   A. Assessment of left ventricular function in a patient with heart failure symptoms

   B. Detection of a pericardial effusion in a patient with nonischemic chest pain

   C. Assessment of tricuspid regurgitation in a patient with a holosystolic heart murmur

   D. Detection of left atrial appendage thrombus prior to cardioversion

The next three questions (Questions 10-12) relate to the following vignette:

A 56-year-old woman presents to her primary care physician (PCP) with complaints of nausea and diaphoresis that occur with physical exertion but are relieved by rest. Her physical activity has been limited by osteoarthritis but she recently started swimming at the local community center, where she first noticed her symptoms. She is a former smoker but quit 5 years ago when she was diagnosed with high blood pressure. Since her symptoms are not characteristic of typical angina, her PCP considers her to be at low-to-intermediate risk of coronary artery disease (CAD) and refers her to a cardiologist for further evaluation.

10. Which of the following would be an appropriate initial test for ischemia in a patient at low-to-intermediate risk of CAD?

    A. Echocardiogram

    B. Left heart catheterization

    C. Cardiac stress test

    D. Cardiovascular magnetic resonance imaging

11. Which of the following procedures for assessing CAD is noninvasive but requires the use of radiocontrast dye?

    A. Left heart catheterization

    B. Cardiac computed tomography

    C. Electrocardiogram

    D. Exercise stress test

12. If the patient is referred for cardiac catheterization, which of the following tests may be performed during the procedure if initial findings on angiography are indeterminate?

    A. Fractional-flow reserve

    B. Myocardial perfusion imaging

    C. Multiple gated blood pool imaging

    D. Coronary artery calcium score

13. Which of the following conditions is not assessed via right heart catheterization?

    A. Heart transplant rejection

    B. Pulmonary arterial hypertension

    C. Acute decompensated heart failure

    D. Acute coronary syndrome

The next two questions (Questions 14 and 15) relate to the following vignette:

A 48-year-old man with a history of hypertension is transferred to your facility after presenting to an outside hospital with acute decompensated heart failure (ADHF). His left ventricular ejection fraction (LVEF) on echocardiogram is 15% (0.15). Shortly after arrival, a left heart catheterization is performed, which reveals only nonobstructive coronary artery disease. Despite aggressive diuretic therapy, the patient's symptoms improve only minimally, prompting the placement of a pulmonary artery (PA) catheter. Initial readings are significant for a pulmonary capillary wedge pressure (PCWP) of 24 mm Hg, cardiac index (CI) of 1.8 L/min/m^2 (0.03 L/s/m^2), and a systematic vascular resistance (SVR) of 1150 dynes·sec/cm^5 (115 MPa·s/m^3).

14. Which of the following is true based on the patient’s PA catheter readings?

   A. The PCWP is elevated, suggesting the patient is volume overloaded.

   B. The SVR is low, suggesting the patient has vasodilatory shock.

   C. The CI is normal, suggesting the patient does not have low output ADHF.

   D. The PA catheter readings cannot be interpreted because the patient’s LVEF is 15% (0.15).

15. The patient’s condition improves and the team would like to investigate for potential causes of his nonischemic cardiomyopathy. Which of the following tests would be preferred for determining if the patient has an infiltrative etiology (eg, sarcoidosis)?

   A. Cardiac magnetic resonance imaging

   B. Pharmacologic stress test

   C. Chest radiography

   D. Intravascular ultrasound

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Traditional risk factors for cardiovascular disease (CVD) include age, sex, and race/ethnicity. Guidelines now recognize a list of “risk-enhancing factors” that can be used to further individualize risk, especially when traditional risk calculators produce an indeterminate result. Example risk-enhancing factors include a family history of premature CVD in a first-degree relative, chronic kidney disease, metabolic syndrome, and premature menopause. See Table e29-2 for a comparison of traditional risk factors and risk-enhancing factors for CVD.

2. **B.** Pain relief with a change in position is more likely to occur with pericarditis or other inflammatory conditions and not with ischemic chest pain. Ischemic chest pain is more likely to be relieved by rest. See the section on chest pain for more information.

3. **A.** The blood pressure should be measured in both arms at the first visit and the arm that gives the *higher* reading should be used for subsequent visits. Recommendations for obtaining an accurate blood pressure reading can be found in Table e29-4.

4. **D.** Orthopnea refers to dyspnea symptoms that occur when lying down, and it can be quantified by asking patients how many pillows are required to sleep comfortably. Patients should also be asked why such elevation is necessary, as multiple pillows may be used for reasons other than relief of dyspnea. See the “Dyspnea” section for more information.

5. **B.** A normal jugular venous pressure is less than 5 cm, which accounts for the distance between the right atrium and the sternal notch. Numbers in excess of 5 cm are indicative of volume overload. An S_2 heart sound and negative abdominojugular reflux are normal findings and wheezes are often characteristic of noncardiac disease. See the “Inspection” and “Auscultation” sections for more information.

6. **C.** The presence of a femoral artery bruit, especially in the absence of lower extremity pulses, is strongly suggestive of peripheral artery disease and should warrant further evaluation. See the “Auscultation” and “Inspection” sections for more information.

7. **C.** Brain natriuretic peptide (BNP) is released following stretch-related injury to myocardial tissue and is strongly suggestive of heart failure; consequently, the absence of an elevated BNP makes heart failure an unlikely cause of dyspnea. See the “B-Type Natriuretic Peptide” section for further discussion.

8. **A.** The PR interval represents the heart’s electrical impulse as it moves across the atrioventricular (AV) node. First-degree AV block can be detected as a prolonged PR interval. See the “Electrocardiography” section for more information.

9. **D.** Although a transesophageal echocardiogram (TEE) is more invasive than a transthoracic echocardiogram (TTE), it may be required to visualize posterior aspects of the heart, such as the left atrial appendage. Since a thrombus may be dislodged from the left atrial appendage during cardioversion, a TEE is often indicated prior to the procedure. See the “Echocardiography” section for more information.

10. **C.** Since the patient is asymptomatic and low-to-moderate risk for coronary artery disease (CAD), a noninvasive test such as a stress test is preferred as the initial modality for assessing ischemia. A pharmacologic stress test would be preferred for this patient since her ability to exercise may be limited by osteoarthritis. See the “Stress Testing” section for more information.

11. **B.** Although cardiac computed tomography (CCT) angiography is less invasive than cardiac catheterization, visualization of the coronary arteries via CCT still requires the use of radiocontrast dye. As a result, CCT angiography is not advantageous in a patient with contrast dye-related contraindications to cardiac catheterization (eg, acute kidney injury). See the section on CCT for more information.

12. **A.** In patients with indeterminate findings on angiography via cardiac catheterization, fractional-flow reserve or intravascular ultrasound may be useful for determining whether the patient may benefit from revascularization. See the “Left Heart Catheterization” section for more information.

13. **D.** Patients presenting with an acute coronary syndrome should be evaluated for revascularization using coronary artery angiography, which cannot be performed with a right heart catheterization. Instead, a left heart catheterization should be performed. See the “Left Heart Catheterization” and “Right Heart Catheterization” sections for a discussion of the indications for each.

14. **A.** Of the readings provided by the pulmonary artery catheter, the abnormal values include an elevated pulmonary capillary wedge pressure (PCWP, normal 6-12 mm Hg) and low cardiac index (normal 2.8-4.2 L/min/m^2 [0.047-0.07 L/s/m^2]). An elevated PCWP is suggestive of elevated left ventricular end-diastolic pressure, which indicates volume overload. See the “Right Heart Catheterization” section and Table e29-10 for more information.

15. **A.** Cardiovascular magnetic resonance (CMR) imaging is the modality of choice for diagnosing an infiltrative etiology of nonischemic cardiomyopathy, as it can characterize pathologic changes in myocardial tissue. See the “Cardiovascular Magnetic Resonance Imaging” section for more information.

Chapter e31: Acute Hypertensive Crisis

Jeffrey J. Mucksavage; Danielle M. Tompkins; Eric J. MacLaughlin

KEY CONCEPTS

KEY CONCEPTS

① Hypertensive crisis is an acute condition of very high blood pressure (BP), with either a systolic BP (SBP) > 180 mm Hg, diastolic (DBP) > 120 mm Hg, or both.

② The presence of new or worsening target end-organ damage differentiates hypertensive emergency from hypertensive urgency.

③ Autoregulation of perfusion is a key physiological concept that explains the pathophysiology of hypertensive crisis.

④ The affected organs during a hypertensive emergency commonly include the heart, lungs, brain, vasculature, kidneys, and eyes.

⑤ Hypertensive urgency does not require rapid (ie, immediate) BP reduction because the benefit does not outweigh the risk. A more gradual BP reduction over several hours to days is optimal. Hypertensive urgency is managed by resuming omitted antihypertensive therapy, increasing current doses of antihypertensives, or adding additional agents to achieve control.

⑥ Hypertensive emergency is a medical emergency that requires acute hospitalization, frequent monitoring, and, in most cases, intravenous (IV) antihypertensive therapy to control BP.

⑦ The goal for managing hypertensive emergencies is to prevent additional organ damage. Target BP goals are different than those for chronic treatment of high BP, and the timeframe for achieving goals is determined by the organ systems affected and comorbities.

⑧ Despite no clear mortality benefit with the use of IV antihypertensive agents, their use is still the standard of care intended to reduce further organ damage. There are multiple IV antihypertensive infusions to choose from. The type of organ damage present, clinical characteristics of the patient, and pharmacological properties of the medication should guide therapy selection.

⑨ Medication nonadherence is a modifiable risk factor that commonly leads to hypertensive crises. Interventions aimed at improving adherence (eg, patient education regarding the importance of medication adherence, simplification of medication regimens, use of fixed-dose combination antihypertensives products, use of low-cost generic agents) and periodic, scheduled follow-up are essential.

BEYOND THE BOOK

BEYOND THE BOOK

To improve your ability to identify the clinical nuances encountered when treating patients with hypertensive crises and also aid in your understanding of the concept of autoregulation, please listen and watch the podcast and video below.

1. Hypertensive Emergencies Demystified: A Brief Clinical Review on the management of hypertensive crisis—HelixTalk: https://www.rosalindfranklin.edu/academics/college-of-pharmacy/helixtalk/helixtalk-episode-134-hypertensive-emergencies-demystified-a-brief-clinical-review/ (total podcast duration: 43:34)
    - The discussion of hypertensive emergency uses an illustrative case in which a patient presents with acute ischemic stroke to highlight the complexities in care with which these patients present.
    - While the total podcast duration is 43:34, focus on the key elements of the podcast highlighted below (total duration: 15:37):
        - Definitions and case presentation: 0:00 to 5:55
        - Discussion of blood pressure and stroke: 29:30 to 33:10
        - Patient management and conclusion: 37:20 to 43:22
2. Autoregulation—Baroreceptors—Rishi Desai (Khan Academy): https://www.youtube.com/watch?v=R07V4NOwfsk&t=602s (duration: 12:08)

INTRODUCTION

As implied by its nomenclature, an acute hypertensive crisis is both a temporal and numerical characterization of dangerously elevated blood pressure (BP) that requires prompt assessment and clinical intervention. However, this broad terminology does not distinguish between patients who require chronic versus emergent interventions to control BP and prevent or minimize complications. For example, some patients with acute hypertensive crisis require emergent escalation to intensive care and intravenous (IV) antihypertensive therapy while others can be managed less aggressively by resuming or adjusting chronic antihypertensive treatment and monitoring.

①② The American College of Cardiology (ACC) and the American Heart Association (AHA) characterize an acute hypertensive crisis as a rapid onset of very high BP (systolic [SBP] > 180 mm Hg and/or diastolic [DBP] > 120 mm Hg).[1] While the joint guidelines by the European Society of Cardiology and the European Society of Hypertension define the BP values slightly differently (SBP ≥ 180 mm Hg and DBP ≥ 110 mm Hg), both the European and American guidelines agree on further characterizing patients based on clinical presentation rather than just a BP reading alone.[1,2] Patients with acute hypertensive crisis and evidence of new or worsening target organ damage are further characterized as a *hypertensive emergency* while those without evidence of target organ damage are characterized as a *hypertensive urgency*. Both conditions require acute attention and evaluation, and the treatment algorithms differ based on clinical presentation.

There is debate about the most appropriate terminology to use when characterizing acute hypertensive crisis. In clinical practice, indiscriminate use and interpretation of the nomenclature confound patient evaluation and treatment decisions. Improper management of an acute hypertensive crisis can lead to serious adverse outcomes. Therefore, clinicians need to clearly understand the guideline-based definitions, use consistent and appropriate terminology when communicating to other providers about patients with acute hypertensive crisis, and, most importantly, manage these patients safely and effectively. This chapter will use guideline-based definitions to help clinicians identify, characterize, and manage an acute hypertensive crisis.

EPIDEMIOLOGY

Estimates of the prevalence of hypertensive crisis and, more specifically, hypertensive urgencies and emergencies, are difficult to describe due to variations in definitions of the condition. Approximately 5 out of every 1,000 patients admitted to the emergency department present with a hypertensive crisis.[3] Two out of 1,000 admissions to the emergency department are diagnosed with a hypertensive emergency.[4] For patients with a previous diagnosis of hypertension, 6 out of 1,000 admissions to the emergency department present with a hypertensive emergency.[4] Of all patients with hypertensive crisis, approximately 60% to 75% of these patients present with hypertensive urgency versus 25% to 40% who present with a hypertensive emergency.[5] Demographically, there is an unclear relationship with gender though some believe there are slightly more cases in women.[6] Patient characteristics associated with the most risk include advanced age (eg, 65 years or older), Black ancestry, and low income (eg, lowest quartile of income).[4,6]

Clinical outcomes associated with acute hypertensive crisis are poor. The estimated one-year mortality rate is over 79% for untreated patients.[7] Patients admitted with hypertensive crisis to emergency departments have a 90-day hospital readmission rate and mortality of 37% and 4.6%, respectively, underscoring the burden and impact of this condition.[8]

ETIOLOGY

The etiology of acute hypertensive crisis is often medication-related, although other causes are possible. Medication nonadherence is the single most common risk factor for acute hypertensive crisis.[9] In addition, the withdrawal effects precipitated by missing doses of certain antihypertensives, such as β-blockers and clonidine, may exacerbate a hypertensive crisis. Drug–drug or drug–disease state interactions (eg, sympathomimetic medications) and the use of illicit substances with vasoactive effects (eg, cocaine, methamphetamine, ecstasy) can also be sources of a medication-related hypertensive crisis. Secondary causes of hypertensive crises include alcohol withdrawal, pheochromocytoma, obstructive sleep apnea, renal artery stenosis, severe thyroid disorders, and hyperaldosteronism.[10] Common medical and pharmacological causes for hypertensive crisis are summarized in Table e31-1.

TABLE e31-1

Common Medical and Pharmacological Causes of Hypertensive Crisis

Medical	
Organ System	**Causative Examples**
Brain	Ischemic or hemorrhagic stroke
Lungs	Obstructive sleep apnea
Heart	Primary hypertension
Kidney	Renal artery stenosis
Endocrine	Hyperaldosteronism, pheochromocytoma, Cushing syndrome, severe thyroid disorders
Pharmacological	
Condition	**Causative Examples**
Nonadherence with prescribed antihypertensive therapy	Patient misconceptions
	Lack of access
Withdrawal of antihypertensive therapy	β-blockers, clonidine
Vasoactive substances	Cocaine, amphetamines, ecstasy
Acute withdrawal of substances and medications	Ethanol, opioids
Drug–drug interactions	Serotonin syndrome
Drug–food interactions	Tyramine containing foods with monoamine oxidase inhibitors
Drug–disease state interactions	NSAIDs, sympathomimetics in patients with hypertension

NSAIDs, nonsteroidal anti-inflammatory drugs.

Data from References [30,31].

PATHOPHYSIOLOGY

3 The pathophysiology of acute hypertensive crisis is multifactorial. Although not fully understood, failure of autoregulation of blood flow and inappropriate activation of the renin–angiotensin–aldosterone system (RAAS) likely play key roles in developing hypertensive crisis.[12] Several medical and pharmacological conditions may lead to sympathetic hyperactivity and result in severe elevations in BP. Examples of these conditions include pheochromocytoma, acute intoxication or withdrawal of certain medications, and obstructive sleep apnea. Pheochromocytomas (adrenal tumors) and paragangliomas (non-adrenal tumors) both release catecholamines (epinephrine, norepinephrine, and dopamine). These catecholamines bind to α_1

receptors on vascular smooth muscle, causing vasoconstriction, and β_1 receptors on the heart, causing tachycardia.[13] Similarly, intoxication with cocaine, amphetamines, or other sympathomimetic medications also increases catecholamines causing similar effects. Withdrawal of substances and medications that blunt the sympathetic nervous system (eg, ethanol, opioids, clonidine, β-blockers) can cause an abrupt rebound of catecholamine release and subsequent hypertensive crisis.[14] Additionally, obstructive sleep apnea enhances sympathetic outflow and catecholamine release, which increases BP. Both renal artery stenosis and hyperaldosteronism upregulate the RAAS, leading to vasoconstriction, sodium and water retention, and subsequent BP elevations.[10] For a more detailed explanation of the pathophysiology of hypertension, please see Chapter 30, “Hypertension.”

② While these mechanisms may lead to acute elevations of BP, the additional pathophysiological changes precipitated by target organ damage may further contribute to the overarching pathophysiology of the disease.[15] Thus, the pathophysiology of acute hypertensive crisis is best understood by categorizing it as hypertensive urgency or hypertensive emergency and, in the case of a hypertensive emergency, subclassifying further by the type(s) of organ damage present.

Autoregulation of Blood Pressure

③ ④ The concept of autoregulation is a key component of the pathophysiological mechanism underlying hypertensive emergency. Under normal physiologic circumstances, autoregulation maintains stable blood flow to organs despite alterations in perfusion pressure via alterations in vascular resistance. In response to changes in BP, autoregulation typically maintains perfusion pressure and blood flow to organs when BP is below 180/120 mm Hg for patients with usually well-controlled BP. Autoregulation curves may vary depending on the patient’s baseline average BP (Fig. e31-1). Patients with sustained, uncontrolled hypertension tend to have rightward shifts of the autoregulation curve and can typically tolerate higher BP than patients with normal BP at baseline.[16] Once a patient-specific critical point on the autoregulation curve is reached, excessive vasoconstriction will decrease perfusion to vital organs. Additionally, there may be areas where blood vessels can no longer maintain adequate resistance and vasodilation occurs. This abrupt vasoconstriction and isolated areas of vasodilation may lead to precipitous drops in perfusion and contribute to target organ dysfunction.[12] Organs most susceptible to dysfunction due to an acute hypertensive crisis include the heart, arterial vasculature, brain, kidney, and eyes (Fig. e31-2).

Additionally, target end-organ damage may be caused by the overactivation of the RAAS pathway. Decreases in perfusion may cause upregulation of the RAAS mechanisms, which further increase vasoconstriction. The resulting increase in vasoconstrictive peptides, including angiotensin II, norepinephrine, endothelin, and antidiuretic hormone, worsen local tissue ischemia. Excessive vasoconstriction also leads to endothelial damage, platelet activation and aggregation, and further target organ dysfunction.[16]

Hypertensive Urgency

Patients with hypertensive urgency present with extreme elevations in BP *without* signs or symptoms of new or worsening target organ dysfunction. However, these patients are at risk of impending target organ dysfunction because of severe BP elevations. Commonly, the elevations of BP seen during hypertensive urgency are secondary to antihypertensive therapy being withdrawn.[1]

Hypertensive Emergency and Target Organ Dysfunction

④ In the setting of hypertensive emergency, target organ dysfunction represents an acute change in organ function from baseline. For example, a patient with no prior history of kidney disease may present with acute kidney injury secondary to severe elevations in BP which would qualify as a hypertensive emergency. In contrast, acute elevations in BP in a patient with a history of chronic kidney disease (CKD) secondary to longstanding hypertension should only be classified as a hypertensive emergency if chronic kidney function is worsening or if new target organ dysfunction is identified. In this section, types of target organ dysfunction will be further summarized.

Cardiovascular

Myocardial Infarction

Acute elevations in BP can lead to endothelial damage in coronary arteries. Subsequent activation of the coagulation cascade and platelet aggregation can lead to ischemia and further release of vasoactive peptides, potentiating the endothelial damage. Ischemia may irreversibly lead to infarction of the myocytes if BP is not rapidly controlled.[15]

Acute Decompensated Heart Failure

Patients presenting with acute decompensated heart failure (ADHF) may have underlying reduced or preserved ejection fraction. Patients with a history of baseline heart failure, including systolic or diastolic dysfunction, are at a higher risk for ADHF from severe hypertension due to the inability of the left ventricle to overcome increased afterload, the pressure that the heart must overcome to achieve adequate cardiac output. Acute increases in afterload place patients at risk for pulmonary edema.[15]

Aortic Dissection

Aortic dissection can result from shear stress on the aortic wall. Over time, elevated BP can lead to tearing of the intima, or the innermost layer, of the aorta, which allows blood to pool in the aortic wall and form a “false lumen.” This reduces the critical supply of blood flow to organs relying on downstream perfusion. Arterial branches of the aorta may also become compressed as the dissection extends distally, leading to organ ischemia.[19]

Neurological

Acute Stroke

Cerebral autoregulation typically allows for constant cerebral blood flow in the capillaries from a mean arterial pressure (MAP) of 60 to 150 mm Hg. When the BP exceeds this upper limit, progressive vasoconstriction and areas of vasodilation can occur. Cerebral ischemia may result from this disrupted autoregulation and endothelial injury resulting from sustained elevations in BP. Areas of vasodilation can also lead to disruptions of the blood-brain barrier, cerebral edema, and microhemorrhages. Additionally, a complicating factor in ischemic stroke is that acute BP lowering can increase ischemia, especially in the penumbra surrounding the ischemic core. High BP may also lead to a hemorrhagic transformation of the ischemic area or cause continued bleeding in the setting of intracerebral hemorrhage (ICH) or subarachnoid hemorrhage.[19,20]

Hypertensive Encephalopathy

Disruptions in the blood-brain barrier and cerebral edema secondary to severely elevated BP may lead to a condition known as hypertensive encephalopathy.[19] This is thought to occur as a result of the elevated BP exceeding the brain’s ability for autoregulation. Increased vascular permeability causes extravasation of intravascular fluid into the brain, which leads to a broad range of nonspecific neurological symptoms.[16]

Kidney

Acute Kidney Injury

Patients with chronic uncontrolled hypertension are predisposed to endothelial dysfunction in the renal arteries, including the afferent arteriole. The resultant structural changes can lead to progressive narrowing of vessels and fibrosis, which impair the autoregulation mechanisms of the kidney. During acute, severe elevations in BP, intraglomerular pressure is no longer preserved by autoregulation, leading to acute renal ischemia.[19]

Ocular

Acute Retinopathy

Acute retinopathy is an ocular complication of hypertensive crisis. Patients with acute, severe elevations in BP may develop retinal hemorrhages, exudates, and papilledema due to increased intracranial pressure, leading to rapid and progressive vision loss.[19]

Other

Pre-eclampsia

Pre-eclampsia is defined as BP greater than or equal to 140/90 mm Hg on two readings at least 4 hours apart any time after 20 weeks gestation or one reading of 160/110 mm Hg or more plus proteinuria.[21] Other types of maternal target organ dysfunction in this syndrome include acute kidney injury, acute liver injury, neurological complications such as seizures, and hematological complications such as clotting abnormalities. This syndrome is triggered by the release of pro-inflammatory cytokines from the placenta during times of placental stress. These stressors may be multifactorial and include uteroplacental malperfusion and other mismatch states between maternal perfusion and the metabolic demands of the placenta and the fetus. Pre-eclampsia can ultimately lead to maternal and fetal morbidity and mortality if not managed rapidly.[22]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Hypertensive Crisis

General

May appear asymptomatic (hypertensive urgency) or with evidence of target organ dysfunction (hypertensive urgency)

Symptoms

Headache, nausea, vomiting, confusion, epistaxis, shortness of breath, chest pain, dizziness, paresthesia, vision changes

Signs

SBP > 180 mm Hg and/or DBP > 120 mm Hg, focal neurological deficits, crackles on lung auscultation

Routine laboratory tests guided by symptoms

Blood urea nitrogen/serum creatinine with estimated glomerular filtration rate (using CKD-EPI Creatinine Equation 2021 [https://www.kidney.org/professionals/kdoqi/gfr_calculator/formula]), serum electrolytes (sodium, potassium), blood glucose, complete blood counts, toxicology screens, pregnancy tests, cardiac troponins.

Other tests

Electrocardiogram, chest radiographs, fundoscopic examination of the eye, computerized tomography of the head

Target organ damage

- Brain (ischemic or hemorrhagic stroke, encephalopathy, cerebral edema)
- Eyes (papilledema, retinal hemorrhage)
- Heart (acute heart failure, myocardial infarction)
- Vascular (rupture of aneurysm or major vessel dissection)
- Kidney (acute or acute on chronic kidney injury)

The clinical presentation of patients with a hypertensive crisis can vary greatly due to the broad definition of the condition. In addition to the extremely elevated BP, presenting symptoms commonly include headache, epistaxis, shortness of breath, chest pain, neurological deficits such as focal weakness or vision changes, dizziness, or paresthesia.[18,23,24] More specifically, patients with hypertensive *urgency* may present with mild or no symptoms since no target organ damage is present despite the markedly elevated BP. Patients with hypertensive urgency more commonly complain of headaches or non-specific symptoms.[17] In contrast, those with a hypertensive *emergency*, who by definition have acute target organ damage present, are more likely to present with neurological symptoms, dyspnea, and/or chest pain but may also describe other nonspecific symptoms.[17] Clinicians should be aware of the common presenting symptoms and promptly evaluate target organ systems when assessing the patient.

A comprehensive history of medical conditions, surgeries, and medications should be obtained for all patients.[25] This interview should include the onset of any symptoms and concurrent ingestions of any vasoactive substances (eg, prescription medication, non-prescription medications, dietary supplements, herbals, illicit drugs). Nonadherence with prescription BP medications is a common cause of hypertensive crises, requiring clinicians to evaluate and assess adherence.[26] A detailed timeline of the ingestion of any illicit vasoactive substances (eg, cocaine, methamphetamine) is also helpful in determining a cause. Remember to screen carefully for drug–drug and drug–supplement interactions when investigating for acute causation of the hypertensive crisis. A classic drug–food interaction known to cause an acute hypertensive crisis is between tyramine-containing food and monoamine oxidase inhibitors, sometimes known as the “cheese effect.”[27] Tyramine is an amino acid found in various foods, including strong or aged cheeses, fermented foods like sauerkraut and kimchi, aged and fermented meats, tap and unpasteurized beer, and pickled herring.[28] The enzyme monoamine oxidase A can prevent the absorption of tyramine by metabolizing it in the gut wall. In the presence of a nonselective monoamine oxidase inhibitor (eg, selegiline, phenelzine, tranylcypromine, isocarboxazid), tyramine is absorbed systemically and converted to norepinephrine, which causes a significant acute elevation in BP.[28] Lastly, recent changes in dietary behavior may also be useful information to obtain for additional reasons. For example, acute changes in dietary sodium intake (eg, recent large-sodium meal) may be a causative factor in precipitating a hypertensive crisis in sodium-sensitive or at-risk patients.[26]

Blood Pressure Assessment

Obtaining accurate BP reading in patients being evaluated for hypertensive crisis is critical. Factors such as poor assessment technique can lead to misdiagnosis and inappropriate treatment of elevated BP. Unfortunately, initiating inappropriate treatment interventions in response to an inaccurately measured BP reading can cause harm. Thus, clinicians should observe and verify that appropriate techniques were used to measure BP before recommending treatment regimens. Knowledge of the correct techniques can help clinicians troubleshoot in patients where traditional BP assessments may be challenging, not possible, or not recommended to ensure accurate BP measurements are recorded. Some examples include patients who are obese or underweight, patients with upper extremity amputation, and patients with certain post-surgical conditions (eg, mastectomy, presence of an arteriovenous fistula). Chapter 30, “Hypertension,” contains a more detailed discussion regarding BP measurement techniques.

Clinicians should resist the temptation to react aggressively to a single elevated BP reading. A single BP value may not be the best indication of the overall clinical picture. For example, a patient presenting in acute pain or with anxiety may exhibit an elevated BP with no other symptoms of target end-organ damage. In these cases, hypertension is manifesting as a symptom of a painful event or anxiety. With appropriate treatment of the pain or anxiety, elevations in BP attributable to those conditions may quickly normalize. However, patients with an extremely elevated BP must receive prompt attention and further clinical follow-up. Since the clinical situations in which patients with reportedly high BP can vary greatly, a clinician must evaluate each elevated value in the context of the patient’s clinical situation, symptoms, and medical history. A high BP reading should be repeated minimally two to three times about 1 to 2 minutes apart and averaged to assess the clinical situation more accurately.[26] Clinicians should also check BP readings on both arms.[29] A significant difference between the two readings may indicate an aortic dissection, a medical emergency requiring immediate workup, and a compelling indication for rapid BP lowering.

Target Organ Damage Assessment

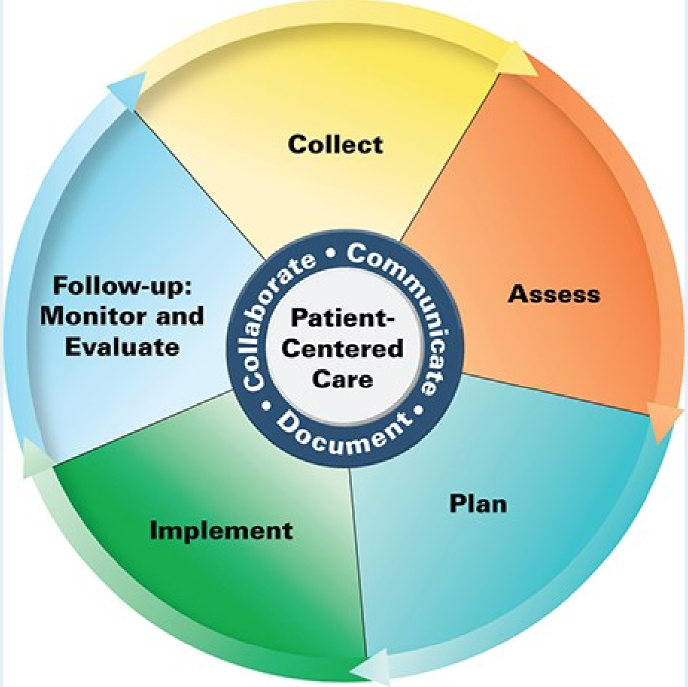
The hallmark of managing a hypertensive crisis is differentiating between hypertensive urgency and hypertensive emergency. This differentiation will ultimately guide clinicians to an appropriate treatment regimen. It is important to note the time course of the elevation of the BP. Patients not known to be hypertensive can present with target organ damage if the BP elevation is rapid and acute. Target organ damage may occur in patients that do not meet the traditional BP parameters used to define a hypertensive crisis. Additionally, patients with chronic hypertension may be conditioned to high pressures via shifts in autoregulation and can present with no symptoms. Therefore, reliance on BP readings alone to diagnose and manage hypertensive crises can be misleading and potentially lead to adverse outcomes due to inappropriate treatment decisions. The patient’s history of present illness, the time course of the BP elevation, and presenting symptoms are good clues to the potential presence of target organ damage and the need for emergent interventions. However, some symptoms can be nonspecific. Therefore, a systematic approach to evaluation is helpful to minimize the risk of missing an affected organ system.

A systematic approach to patient evaluation generally starts from the top-down, commencing with a neurological assessment. Patients should be evaluated for any focal neurological deficits which may be indicative of a stroke. Common signs of stroke include facial asymmetry, unilateral weakness or paresthesia, confusion, visual changes, dizziness or imbalance, or a sudden headache. Another non-stroke neurological condition presenting as a hypertensive emergency is hypertensive encephalopathy. Hypertensive encephalopathy, which is the result of cerebral edema and elevations in intracranial pressure, may manifest as headache, vomiting, confusion, visual changes, seizures, and coma. This diagnosis should be considered after other conditions have been eliminated from the differential diagnosis.[16] Neurological imaging may assist with diagnosing both stroke and hypertensive encephalopathy and is required in patients presenting with neurological symptoms.[29] Fundoscopic examination of the eye is another important means to evaluate target organ damage and should be part of a patient’s clinical workup.[29] Important clinical findings from fundoscopic examination include arteriolar narrowing, retinopathy, hemorrhages (flame, blot, or dot), and papillary edema.[12,25,29] If the patient reports chest pain, acute coronary syndrome (ACS) should be on the differential diagnosis prompting a more detailed evaluation of symptoms, including onset, quality, duration, and precipitating and mitigating factors. Complaints of shortness of breath should be followed up with evaluations of oxygen saturation and auscultation of the lungs. Crackles on auscultation may be a sign of pulmonary edema and potentially heart failure. A chest radiograph assists in confirming the diagnosis of heart failure. Peripheral edema in the extremities and jugular venous distention can also be signs of volume overload and cardiac failure. An electrocardiogram is needed to detect cardiac ischemia and arrhythmias from ischemia or heart failure. An echocardiogram can confirm the clinical findings of cardiac dysfunction. Discordance between BP readings taken on different extremities may suggest an aortic dissection prompting an additional emergent workup.[16] An abdominal examination is also necessary to evaluate for aortic aneurysms.[12]

Laboratory assessment of patients presenting with a hypertensive crisis is critical to detecting target organ damage and selecting appropriate pharmacotherapy. Basic metabolic panels including electrolytes, glucose, serum creatinine, and complete blood cell counts are useful initial laboratory assessments.[16,29] An evaluation of kidney function is essential since the kidneys are at-risk organs. Evidence of acute kidney injury or acute-on-chronic kidney injury is important to detect since kidney disease is common in this population and may inform pharmacotherapy decisions.[29] Therefore, it is important to evaluate current serum creatinine and previously reported values to note trends in kidney function. New or worsening hematuria and proteinuria on urinalysis are indicative of kidney damage. Laboratory evidence consistent with acute kidney damage or acute-on-chronic kidney injury (eg, acute elevations in serum creatinine in patients with CKD) would be sufficient to classify a hypertensive emergency. Chapter 30, "Hypertension," contains a complete discussion of the laboratory assessment necessary in patients that require further diagnosis of secondary causes of hypertension. Patients suspected of illicit drug use should have a toxicologic urinalysis to confirm the presence of causative substances. In women of childbearing age, pregnancy tests are also necessary to assist with the diagnosis of pre-eclampsia or eclampsia and guide pharmacotherapy decisions with the safety of the fetus in mind. Patients who are pregnant with acute onset severe hypertension during their pregnancy require a specific workup for pre-eclampsia due to the high maternal and fetal risk for morbidity and mortality. In the absence of proteinuria, the diagnosis can be made with new onset of thrombocytopenia (platelet count $< 100{,}000/\text{mm}^3$ [100×10^9/L]), renal insufficiency (serum creatinine > 1.1 mg/dL [97 µmol/L] or doubled from baseline), impaired liver function (transaminases two times the upper limit of normal), pulmonary edema, or new-onset headache unresponsive to medication and not due to an alternative diagnosis. Pre-eclampsia can be further categorized by the presence of severe features which include BP of 160/110 mm Hg or more on two readings at least 4 hours apart, thrombocytopenia, renal insufficiency, impaired liver function (elevated transaminases as above or severe persistent right upper quadrant or epigastric pain unresponsive to medications), or visual disturbances. Eclampsia occurs when there are new-onset tonic-clonic, focal, or multifocal seizures that can not be explained by other conditions (eg, epilepsy, stroke, drug use).

PATIENT CARE PROCESS

Patient Care Process* for the Management of Hypertensive Crisis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, sex, pregnancy)
- Patient history (past medical/surgical, family, social, eg, dietary habits, tobacco use, alcohol use, illicit use)
- Blood Pressure (BP) readings (when, how obtained, usual BP range)
- Current or recent use of prescription medications or substances (eg, prior antihypertensive medication use, over-the-counter medications, dietary supplements, illicit substances)(Table e31-1)
- Objective data
    - BP, heart rate (HR), height, weight, and BMI
    - Physical exam results (chest auscultation, fundoscopic exam, neurological exam)
    - Labs (eg, serum electrolytes, SCr, blood urea nitrogen)
    - Other diagnostic tests when indicated (eg, ECG, echocardiogram, brain imaging)

Assess

- Presence of target end-organ damage (eg, myocardial infarction, stroke, new or worsening kidney function) (Fig. e31-2)
- Adherence to antihypertensive medications
- Drug–drug, drug–food, and drug–disease state interactions that cause hypertension
- BP goal and timeframe to achieve the goal based on target end-organ damage
- Appropriate antihypertensive infusion(s), if necessary, to achieve BP goals
- Appropriateness and effectiveness of the current antihypertensive regimen

Plan[*]

- Medication therapy regimen including specific antihypertensive(s), dose, route, frequency, and duration; specify the continuation and discontinuation of existing therapies (Table e31-3)
- Monitoring parameters including efficacy (eg, BP, cardiovascular events, kidney health), safety (medication-specific adverse effects, new or worsening tissue ischemia), and timeframe
- Patient education (eg, the purpose of treatment, dietary and lifestyle modification, medication therapy, adherence)
- Referrals to other providers when appropriate (eg, physician, dietician)
- Appropriate transition from parenteral to oral antihypertensive therapy

Implement[*]

- Facilitate medication administration in a timely manner (Table e31-2)
- Communicate dosing, titration, and monitoring parameters of acute antihypertensive therapy with clinical team
- Use motivational interviewing and coaching strategies to maximize medication adherence

Follow-up: Monitor and Evaluate

- Determine BP goal attainment and resolution of target end-organ damage (Fig. e31-3)
- Presence of adverse effects

[*] *Collaborate with patients, caregivers, and other healthcare professionals.*

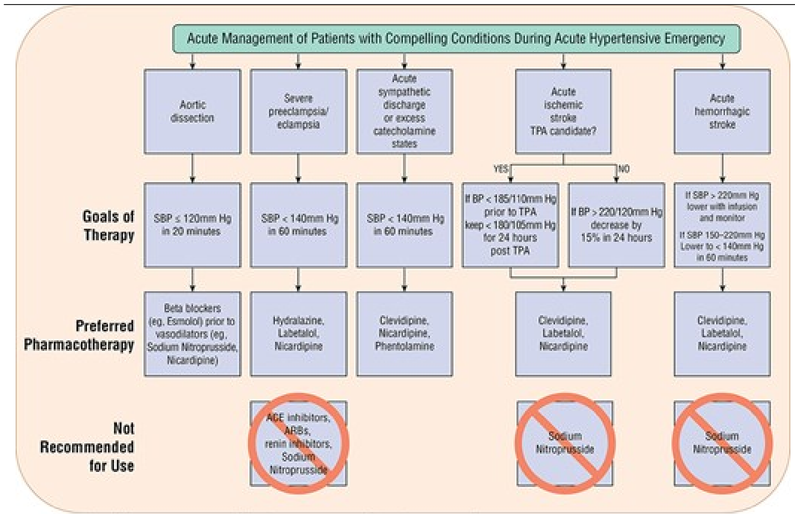
TREATMENT

Treatment Goals

⑦ ⑧ The goals of treatment for patients presenting with hypertensive crises are to carefully assess and characterize the degree of hypertension, evaluate for any precipitating risk factors, characterize the condition as hypertensive urgency or emergency based on the presence of acute target organ damage, and safely reduce the BP to specific goals in an appropriate timeframe, based on compelling indications.[1] Ultimately, clinical goals, including the selection of appropriate BP targets, are determined by the classification (hypertensive urgency or emergency) and the presence of compelling indications. In patients with evidence of acute target organ damage (hypertensive emergency), the primary goal is to avoid further worsening the organ damage by lowering BP quickly and safely. Since the long-term consequences of a further worsening of organ damage can have profound clinical impacts, selecting the right treatment course is paramount. Selecting appropriate pharmacotherapy based on the presence of compelling indications, clinical presentation, and pharmacological properties of the antihypertensives may minimize long-term health consequences (Fig. e31-3).[1,29]

FIGURE e31-3

Summary of treatment recommendations for hypertensive emergencies based on specific target organ damage. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; SBP, systolic blood pressure; TPA, tissue plasminogen activator)



Acute Management of Patients with Compelling Conditions During Acute Hypertensive Emergency
Aortic dissection
Severe preeclampsia/ eclampsia
Acute sympathetic discharge or excess catecholamine states
Acute ischemic stroke TPA candidate?
Acute hemorrhagic stroke
YES
NO
Goals of Therapy
SBP ≤ 120mm Hg in 20 minutes
SBP < 140mm Hg in 60 minutes
SBP < 140mm Hg in 60 minutes
If BP < 185/110mm Hg prior to TPA keep < 180/105mm Hg for 24 hours post TPA
If BP > 220/120mm Hg decrease by 15% in 24 hours
If SBP > 220mm Hg lower with infusion and monitor
If SBP 150–220mm Hg Lower to < 140mm Hg in 60 minutes
Preferred Pharmacotherapy
Beta blockers (eg. Esmolol) prior to vasodilators (eg. Sodium Nitroprusside, Nicardipine)
Hydralazine, Labetalol, Nicardipine
Clevidipine, Nicardipine, Phentolamine
Clevidipine, Labetalol, Nicardipine
Clevidipine, Labetalol, Nicardipine
Not Recommended for Use
ACE inhibitors, ARBs, renin inhibitors, Sodium Nitroprusside
Sodium Nitroprusside
Sodium Nitroprusside

Blood Pressure Goals

Hypertensive Urgency

5 Hypertensive urgency is characterized as patients presenting with BP elevations greater than 180/120 mm Hg without the presence of target organ damage. Despite using the term “urgency” in the description of the condition, there is little data to support that patients with hypertensive urgency are at acute, urgent risk for negative sequelae.[30] For example, a review of patients with hypertensive urgency presenting to outpatient care centers found the rate of major adverse cardiovascular events within seven days to be low (<0.5%) in patients admitted to the hospital and an even lower (<0.1%) in patients sent home.[31] While patients with hypertensive urgency are at risk of the long-term adverse effects of uncontrolled hypertension, in the short term, these risks are minimal in the absence of acute target organ damage. In fact, the consequences of acutely and aggressively lowering BP in patients with hypertensive urgency, such as ischemic stroke, myocardial infarction, and renal ischemia, may outweigh any derived benefit. The ACC/AHA Guideline offers no specific BP goal in the acute management of hypertensive urgency.[1] Acute BP lowering, referral to the emergency department, or hospital admission is not recommended for patients with hypertensive urgency.[1]

Hypertensive Emergency

Specific BP goals for patients with a hypertensive emergency are determined by the target organ damage present. Table e31-2 summarizes BP goals for hypertensive emergencies.

TABLE e31-2

Target Organ Damage, Blood Pressure Targets, and Medication Choices for Hypertensive Emergencies

Target Organ Damage	**Blood Pressure Target**	**IV Antihypertensive Selection**
Acute kidney injury	Reduce BP by a max of 25% in the first hour, then to 160/100-110 mm Hg over the next 2-6 hours, then to normal over the next 24-48 hours	Most IV antihypertensives are acceptable Use caution with prolonged use of sodium nitroprusside due to renal clearance of the toxic metabolite thiocyanate Avoid enalaprilat due to the risk of worsening AKI
Acute decompensated heart failure with pulmonary edema	Reduce BP by a max of 25% in the first hour, then to 160/100-110 mm Hg over the next 2-6 hours, then to normal over the next 24-48 hours	Nitroglycerin or sodium nitroprusside (nicardipine and clevidipine are acceptable alternatives) Avoid β-blockers or non-dihydropyridine calcium channel blockers
Aortic dissection	HR < 60 beats per minute AND SBP ≤ 120 mm Hg within the first hour, ideally within the first 20 minutes	Initiate β-blocker before a vasodilator (eg, nicardipine, clevidipine, or nitroprusside) to prevent reflex tachycardia
Intracranial hemorrhage	If SBP > 220 mm Hg lower and monitor; if SBP 150-220 mm Hg, SBP < 140 mm Hg in 60 minutes	Nicardipine, clevidipine, or labetalol
Ischemic stroke	BP < 185/110 mm Hg before starting tPA and < 180/105 mm Hg during tPA infusion. SBP < 220 mm Hg if not receiving tPA	Nicardipine, clevidipine, or labetalol
Hypertensive encephalopathy	Reduce BP by a max of 25% in the first hour, then to 160/100-110 mm Hg over the next 2-6 hours, then to normal over the next 24-48 hours	Most IV antihypertensives are acceptable
Acute coronary syndromes	Reduce BP by a max of 25% in the first hour, then to 160/100-110 mm Hg over the next 2-6 hours, then to normal over the next 24-48 hours	Esmolol, labetalol, nitroglycerin, nicardipine, or sodium nitroprusside Use caution with non-dihydropyridine calcium channel blockers Avoid β-blockers in the setting of reduced ejection fraction, bradycardia (HR < 60 bpm), hypotension (SBP < 100 mmHg), poor peripheral perfusion, second or third-degree heart block, or reactive airway disease
Severe Pre-eclampsia or Eclampsia	SBP < 140 mm Hg in the first hour	Hydralazine, labetalol, or nicardipine Enalaprilat (any ACEi, ARB, renin inhibitors) and nitroprusside contraindicated
Pheochromocytoma crisis	SBP < 140 mm Hg in the first hour	β-blockers ± nicardipine or clevidipine
Retinopathy	Reduce BP by a max of 25% in the first hour, then to 160/100-110 mm Hg over the next 2-6 hours, then to normal over the next 24-48 hours	Most IV antihypertensives are acceptable Avoid fenoldopam

ACEi, angiotensin-converting enzyme inhibitor; AKI, acute kidney injury; ARB, angiotensin receptor blocker; bpm, beats per minute; HR, heart rate; tPA, tissue plasminogen activator.

Data from References [1,32-35].

General Approach to Treatment

Prevention

⑨Counseling patients on the importance of medication adherence is a crucial measure in preventing hypertensive crises. Many patients with underlying chronic hypertension are asymptomatic and may not feel compelled to take medications consistently. Importantly, patients must have access to prescribed antihypertensives. Generic medications should be used whenever possible to avoid cost-related barriers to care. Additionally, appropriate nonpharmacological therapy must be recommended for all patients (see Chapter 30, “Hypertension”). Patients should also be instructed to consult with their pharmacist before initiating any new over-the-counter medications, which can potentially lead to poor BP control (eg, nonsteroidal anti-inflammatory drugs [NSAIDs]).

Hypertensive Urgency Treatment

⑤ Patients presenting with hypertensive urgency should be managed conservatively by initiating, reinitiating, or intensifying oral antihypertensive medications and implementing nonpharmacological interventions (eg, sodium restriction, removing medications or other substances that can increase BP). Guideline recommended antihypertensive medications should be chosen whenever possible. These treatments are discussed in more detail in Chapter 30, “Hypertension.” Patients should not be required to seek evaluation in the emergency department unless target organ damage is suspected.[1] Aggressive lowering of BP with IV antihypertensives is not indicated in the absence of target organ damage; the risks associated with precipitous BP drops outweigh any benefit of intensive BP control. Patients with chronically uncontrolled hypertension will have shifts in autoregulation that make intensive BP lowering suboptimal for organ perfusion. Therefore, overly aggressive BP-lowering places patients at risk for ischemic complications. For this reason, a gradual lowering of BP with oral antihypertensives to goal is the safest treatment approach in patients with hypertensive urgency.[36]

Hypertensive Emergency Treatment

⑥⑦⑧ Suspected target organ dysfunction in the setting of extreme BP elevations constitutes a medical emergency and patients should be promptly referred to the emergency department for further management.[1] Because acute target organ disease is present, the benefit of rapid BP lowering with IV antihypertensives generally outweighs the risk of potential ischemic complications described previously. Patients with hypertensive emergency require admission to the intensive care unit to accommodate the frequency of monitoring and administration of antihypertensive therapy via continuous IV infusion. The goal of treatment with IV antihypertensives is to prevent worsening organ dysfunction by targeting specific BP goals. However, treatment with IV antihypertensives has not been proven to reduce mortality in randomized controlled trials.

Pharmacotherapy

General Considerations

⑧ The ideal antihypertensive used to treat hypertensive emergencies should have a fast onset and offset of action, predictable pharmacokinetics, and minimal adverse effects. The route of administration that generally has the most rapid onset is IV, with continuous IV infusions providing the most optimal pharmacokinetics (Table e31-3). Continuous IV infusions of antihypertensive medications allow for the ability to titrate the dose to the desired effect. Thus, doses can be rapidly up-titrated to achieve intensive BP control but if BP decreases too rapidly, the dose of the infusion can also be readily decreased in order to minimize adverse effects related to hypotension such as ischemia. Intermittent dosing of antihypertensives on an as-needed basis is usually not ideal, given that precipitous and unpredictable drops in BP could occur. Rather than maintenance of the BP in a tight range, intermittent dosing causes more variation, and patients may experience more episodes above and below the desired BP range. Some scenarios may warrant intermittent IV boluses of an antihypertensive, however, generally continuous infusions are preferred.

TABLE e31-3

Intravenous Antihypertensive Medications

Medication	Dose	Onset (minutes)	Duration (minutes)	Adverse Effects	Indications and Precautions
Clevidipine	1-2 mg/hr IV infusion (Maximum dose: 32 mg/hr) Dose may be doubled at 90-second intervals toward BP goal; as BP approaches goal, titrate by smaller increments every 5-10 minutes (every 1-2 mg/hr increase in dose will reduce BP by approx. 2-4 mm Hg systolic BP)	2-4	5-15	Hypotension, headache, nausea, tachycardia, hyper-triglyceridemia	Most hypertensive emergencies; caution with coronary ischemia; contraindicated in soy or egg allergy, defective lipid metabolism, and severe aortic stenosis
Enalaprilat	1.25-5 mg IV every 6 hours	15-30	360-720	Hypotension	Acute left ventricular heart failure; avoid in acute myocardial infarction, eclampsia, acute kidney injury; precipitous fall in pressure in high-renin states; variable response
Esmolol	250-500 mcg/kg/min IV bolus (optional), and then 50-100 mcg/kg/min IV infusion; may repeat bolus after 5 minutes or increase infusion to 300 mcg/min Titrate infusion by 50 mcg/kg/min no more than every 4 minutes until at goal	1-2	10-20	Hypotension, bradycardia, nausea, asthma, first-degree heart block, HF	Aortic dissection; perioperative; avoid in patients treated with a β-blocker, bradycardic, or decompensated HF
Fenoldopam	0.1-0.3 mcg/kg/min IV infusion Increase infusion by 0.05-0.1 mcg/kg/min every 15 minutes until at goal	<5	30	Hypotension, tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Hydralazine	10-20 mg IV every 4-6 hours (maximum dose: 40 mg)	10-20	60-240	Hypotension, tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
Labetalol	10-20 IV bolus followed by 20-80 mg every 10 minutes until BP controlled followed by 0.5-2 mg/min IV infusion Increase infusion by 0.5 mg/min every 15 minutes until at goal	5-10	180-360	Hypotension, vomiting, scalp tingling, bronchoconstriction, dizziness, nausea, bradycardia, heart block, orthostatic hypotension	Most hypertensive emergencies except acute HF or heart block
Nicardipine	2.5-5 mg/hr IV infusion Increase infusion by 2.5 mg/hr every 5-15 minutes until at goal	5-10	15-30 (may exceed 240)	Hypotension, tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute HF; caution with coronary ischemia

Nitroglycerin	5-200 mcg/min IV infusion Increase infusion by 5 mcg/min every 3-5 minutes; if no response at a dose of 20 mcg/min, increase infusion by 10-20 mcg/min every 3-5 minutes until at goal	2-5	5-10	Hypotension, headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Sodium nitroprusside	0.25-10 mcg/kg/min IV infusion Increase infusion by 0.5 mg/kg/min every 3 minutes until at goal	Seconds	1-2	Hypotension, nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure, azotemia, or chronic kidney disease

HF, heart failure.

⑤ ⑥ Oral antihypertensives with relatively quick onsets of action have been utilized in the setting of severely elevated BP. The rationale for use in this setting is that these medications correct BP readings more rapidly than oral antihypertensives with longer onset times. However, treatment of asymptomatic severe hypertension (hypertensive urgency) with rapid-acting, "as-needed" oral antihypertensives is not warranted. Instead, guideline-recommended therapies should inform treatment decisions. Additionally, oral antihypertensives should not be used in the setting of target organ damage (hypertensive emergency), as their effects are not as rapid or predictable as IV antihypertensives. Oral antihypertensives should only be utilized if vascular access is unavailable.

Calcium Channel Blockers (CCBs)

Calcium channel blockers (CCBs) act by inhibiting the entry of calcium ions into cells through voltage-gated calcium channels thus preventing cellular depolarization. CCBs can be broadly characterized by their chemical structure as dihydropyridine (DHP) or non-dihydropyridine (non-DHP). DHP CCBs act preferentially on the vascular smooth muscle cells to promote smooth muscle relaxation. They have minimal effect on the calcium channels in the myocytes and, therefore, do not typically have direct effects on heart rate or contractility. Conversely, non-DHP CCBs are more selective for the cardiac myocytes and have more effects on the cardiac conduction system.[37] DHP CCBs are the primary agents from this class used in hypertensive emergencies. Please refer to Chapter 30, "Hypertension," for more information on the types of CCBs.

Nicardipine

Nicardipine, a short-acting IV DHP CCB, has become a mainstay of therapy for hypertensive emergencies due to its pharmacokinetics and predictable pharmacodynamics (eg, effect on BP). Nicardipine crosses the blood-brain barrier and causes cerebral vascular smooth muscle relaxation. Because of these properties, nicardipine is useful in patients with neurological hypertensive emergencies. Nicardipine may have variable effects on cardiac function because it causes coronary artery vasodilation and increases perfusion. However, it may also cause reflex tachycardia, which increases myocardial oxygen demand. The net effect, therefore, tends to be relatively neutral. Nicardipine is contraindicated in patients with severe aortic stenosis. Nicardipine clearance may be affected by severe kidney or hepatic impairment, so titrations should be made more slowly in these patients. During prolonged infusions of nicardipine, patients should be monitored for volume overload because the dilution required for IV administration (0.1 mg/mL) can result in patients receiving nearly 2 liters of fluid during a 24-hour period at high doses. Other common adverse drug reactions associated with nicardipine use include headache, hypotension, and tachycardia.[37,38]

Clevidipine

Clevidipine is an IV DHP CCB that acts as a vasodilator on arterioles. Compared with nicardipine, clevidipine has the added benefit of more rapid onset and offset of action and lack of accumulation in organ impairment. In clinical trials, clevidipine was associated with faster BP control and less precipitous BP drops than other agents.[39,40] However, it was not associated with better clinical outcomes overall. Clevidipine undergoes rapid hydrolysis by plasma esterases to inactive metabolites. Clevidipine is formulated as a lipid emulsion, so caution is warranted when using it for prolonged durations, as hypertriglyceridemia can occur. Additionally, because lipid formulations have a higher risk of bacterial or fungal contamination, lines must be changed every 12 hours to minimize the risk of infection. It is also contraindicated in patients with soy or egg allergy, lipid metabolism defects, or acute pancreatitis in the setting of hyperlipidemia. Clevidipine is also contraindicated in severe aortic stenosis.[37,39,40]

Vasodilators

Nitroglycerin

Nitroglycerin induces smooth muscle relaxation via its conversion to nitric oxide (NO), activating guanylate cyclase and cyclic guanosine 3’,5’-cyclic monophosphate (GMP) in smooth muscle cells, causing vasodilation. Nitroglycerin has a rapid onset and offset, making it useful for emergent use and providing ease of titration. Nitroglycerin is primarily a venodilator. However, it also causes arteriole vasodilation at high doses (>60 mcg/min). Because nitroglycerin is a potent venodilator, cardiac preload reductions can be achieved even at low doses (≤60 mcg/min), making it useful in treating patients with acute HF. It is more challenging to utilize nitroglycerin for other indications (eg, stroke, aortic dissection) due to dose-limiting side effects such as headache and reflex tachycardia. Additionally, tachyphylaxis, or loss of efficacy, can occur relatively quickly during nitroglycerin administration, requiring continuous reassessments for the need to increase the dose. For this reason, IV nitroglycerin should not be used for more than 24 to 48 hours.[37,41] Nitroglycerin and other nitrates are contraindicated in patients who have received phosphodiesterase-3 inhibitors (ie, avanafil, sildenafil, tadalafil, vardenafil) due to the risk of profound hypotension.[42] To avoid this interaction, nitrates should be avoided until at least 12 hours after the last dose of avanafil, 24 hours after the last dose of sildenafil or vardenafil, and 48 hours after the last dose of tadalafil. Nitroglycerin is also contraindicated in patients with known or suspected elevations in intracranial pressure.

Sodium Nitroprusside

Sodium nitroprusside is a prodrug that is converted to its active form via dissociation of NO and cyanide upon interaction with sulfhydryl groups on erythrocytes and other plasma proteins. Similar to nitroglycerin, once NO is released, guanylate cyclase and cyclic GMP are activated in smooth muscle cells, causing vasodilation.[43] Sodium nitroprusside was traditionally used as one of the first-line agents for hypertensive emergency given its potent arteriole and venous dilation effects and short onset and half-life (minutes). However, it is now used less frequently due to several theoretical drawbacks. Accumulation of toxic metabolites, including cyanide, may occur in patients with kidney or hepatic impairment. Normally, the liver converts cyanide to thiocyanate, which is subsequently excreted by the kidneys. In patients with severe liver impairment, cyanide can accumulate, which is 100 times more toxic than thiocyanate, and should be avoided in these patients. With kidney impairment, thiocyanate toxicity can occur. However, because thiocyanate is less toxic than cyanide, the risk of thiocyanate toxicity in patients, including those with kidney impairment, is low when low doses (max dose 2 mcg/kg/min) are administered for short periods (<24 hours). Concerns regarding the possibility of sodium nitroprusside raising intracranial pressure also limit its use in patients with intracranial pathologies at risk for elevations of intracranial pressure. Additionally, in patients with coronary artery disease, redistribution of oxygenated blood from ischemic areas with less vasodilation toward nonischemic regions, a phenomenon known as “coronary steal,” has been reported as a potential concern. Finally, patients with hypovolemia or diastolic dysfunction may experience excessive hypotensive effects with sodium nitroprusside. Although it is used less frequently, the potency of sodium nitroprusside makes it a good option for patients who fail to respond adequately to other IV antihypertensive medications.[37,41]

Hydralazine

Hydralazine is a peripheral arterial vasodilator that is available in both IV and oral formulations. Hydralazine can be administered on an intermittent, as-needed basis, although its use is limited given its unpredictable effects on BP. While onset typically occurs within 30 minutes and the duration of activity is normally 12 hours or less, the effects on BP can persist for up to 100 hours, especially in patients that are slow acetylators. Hydralazine should be avoided in patients susceptible to worsening target organ damage due to the risk of precipitous BP drops. Therefore, hydralazine is not considered first-line therapy. Furthermore, hydralazine has been reported to induce myocardial ischemia in patients who experience rebound tachycardia. For this reason, in patients with a history of cardiac disease, hydralazine should only be used after a β-blocker is administered to avoid rebound tachycardia unless concomitant bradycardia is present.[37,41]

Some clinicians inappropriately use oral hydralazine to treat hypertensive urgency in the hospital setting. Although theoretically useful for acute BP elevations because it produces peak plasma concentrations in 1 to 2 hours, oral hydralazine should generally be avoided due to unpredictable pharmacokinetics and the possibility of prolonged duration of action. Additionally, in the absence of target organ damage, there is currently no indication to treat acutely elevated BP.[44]

Fenoldopam

Fenoldopam is a selective peripheral dopamine type 1 (D_1) receptor agonist. The pharmacologic effect of D_1 receptor stimulation is arterial vasodilation, including those in the renal and mesenteric vasculature. Consequently, fenoldopam reduces BP and preserves renal blood flow. Fenoldopam contains sodium metabisulfite, so it should not be used in patients with sulfite allergies or intolerance. Fenoldopam should also be avoided in patients with increased intraocular pressure, such as glaucoma, as it causes dose-dependent increases in intraocular pressure. It is unclear if fenoldopam affects intracranial pressure, so it should generally be avoided in neurological hypertensive emergencies.[37,45]

β-Blockers

Labetalol

Labetalol is a mixed α_1 and nonselective β_1 and β_2 adrenergic antagonist, with β activity predominating in a 7:1 ratio over the alpha activity for the IV formulation (compared to oral labetalol which has a 3:1 ratio). The selectivity and physiologic effects of labetalol vary depending on the formulation used. Antagonism of α_1 occurs in vascular smooth muscle, decreasing systemic vascular resistance. β_1 antagonism occurs in the myocardium and decreases heart rate and contractility while β_2 antagonism occurs mainly in the pulmonary artery smooth muscle, causing bronchoconstriction (although this is not the predominant effect). Labetalol can be administered as intermittent IV boluses or as a continuous IV infusion. Labetalol bolus dosing is useful as a loading dose preceding a continuous infusion or an intermittent dosing strategy utilized on an as-needed basis. In a true hypertensive emergency, sustained BP control with a continuous infusion is usually more appropriate than intermittent dosing strategies. However, labetalol boluses could also be helpful as add-on therapy when an IV infusion is being used at maximum dosage. Labetalol is useful in situations where heart rate and BP control are both warranted. Labetalol has a longer duration of action (2-4 hours) than other commonly used IV antihypertensives, making titrations more complicated and necessitating more caution when doing so. Generally, other agents such as nicardipine provide more rapid BP control than labetalol. Labetalol is contraindicated in the setting of severe bradycardia, second- or third-degree heart block, ADHF, and reactive airway diseases due to its nonselective β activity.[37,46]

Esmolol

Esmolol is a rapid-acting selective β_1 adrenergic antagonist, with its main effects being heart rate reduction and no effect on systemic vascular resistance. Because of its cardioselectivity, esmolol is typically administered concomitantly with a vasodilating medication to treat hypertensive emergencies. In other words, esmolol is useful as an adjunct when heart rate control is needed in addition to rapid BP reduction but generally cannot achieve adequate reductions on its own. Esmolol should be avoided in patients with bradycardia, second- or third-degree heart block, or ADHF due to its negative chronotropic and inotropic properties. Esmolol is generally well-tolerated in patients with reactive airway disease, given its cardioselectivity.[37,41]

Metoprolol

Metoprolol is a cardioselective β-blocker. IV metoprolol is typically only administered as an intermittent dose and, therefore, is not an ideal medication for BP control in the setting of hypertensive emergencies. Metoprolol may be used to prevent or treat rebound tachycardia associated with vasodilatory antihypertensive medications (eg, hydralazine).[37]

Alternative Medication Classes

Enalaprilat

Enalaprilat is an IV angiotensin-converting enzyme (ACE) inhibitor that exerts its effect via inhibition of the conversion of ACE I into ACE II, which is a potent vasoconstrictor. IV enalaprilat can be administered as an intermittent, as-needed bolus. Peak effects may not be observed until 4 hours after administration and prolonged effects can be observed for up to 12 hours. Thus, it is not an ideal agent for managing a hypertensive emergency. Enalaprilat is contraindicated in the setting of acute kidney injury and hyperkalemia.[37,41]

Clonidine

Like oral hydralazine, oral clonidine is also utilized inappropriately by some clinicians to treat acutely elevated BP in the setting of hypertensive crisis. Clonidine acts via central α_2 agonism to reduce sympathetic outflow, which, in turn, decreases BP. Clonidine is available as an oral tablet and a transdermal patch. In patients with a hypertensive emergency, oral clonidine should only be used if IV access cannot be obtained; the transdermal formulation has no role in the treatment of hypertensive crisis. Oral clonidine has an onset of action of 0.5 to 1 hour with maximum effects at 2 to 4 hours. Clonidine should generally be avoided for long-term use due to the potential for tolerance, hypertensive crisis upon withdrawal of the medication, adverse effects (eg, bradycardia, sedation, dizziness), and lack of outcome data.[47,48] (See Chapter 30, "Hypertension.")

Medications to Avoid

Immediate-release (IR) oral formulations of nifedipine, a DHP CCB, have been used historically to acutely treat elevated BP. Oral and sublingual IR formulations of nifedipine produce rapid and profound BP decreases after administration that has also been reported to cause myocardial ischemia, even at low doses. For this reason, IR nifedipine formulations should not be used in the management of a hypertensive crisis.[48,49]

Compelling Indications

Figure e31-3 summarizes treatment recommendations when specific target organ damage is present.

Intracerebral Hemorrhage (ICH)

Patients with ICH have an increased risk of mortality and functional morbidity. When presenting with this form of stroke, patients also commonly have high elevated BP in the acute setting. Rapid control of BP is thought to reduce mortality and functional morbidity. Because the risk of re-hemorrhage and hematoma expansion may be high in the acute phase of presentation, early control of BP might mitigate this risk and improve functional outcomes. Two landmark trials have examined the effect of early aggressive BP lowering versus a more conservative approach to BP management in this patient population.[50,51] The first of these trials randomized patients to SBP goals of <140 mm Hg or <180 mm Hg via any pharmacological means within 6 hours of stroke onset and reported no difference in the primary outcome of death or severe disability between groups.[50] However, secondary results showed potentially improved functional outcomes in patients in the more aggressively controlled group.

Similarly, the Antihypertensive Treatment of Acute Cerebral Hemorrhage II trial, or ATACH-2, randomized patients to the same BP goals but within 4.5 hours of stroke onset using continuous infusions of nicardipine to meet the BP goals.[51] There was no difference in death or severe disability as the primary outcomes between the two treatment groups. Additionally, there was an increased risk of adverse kidney events within 7 days in patients in the intensive BP lowering group. Due to the inconclusive outcomes of these trials, the ideal BP goal in patients with an ICH is not known.

While the optimal BP target, timing of intervention, and pharmacologic agent of choice for managing elevated BP in patients with ICH remain unclear, major medical organizations offer guidance on acute BP management in this patient population. The 2015 AHA/American Stroke Association (ASA) guideline on the management of spontaneous ICH, published before the results of the ATACH-2 trial were available, recommends an SBP goal of less than 140 mm Hg in patients presenting with SBPs between 150 and 220 mm Hg without any contraindications.[33] In patients presenting with SBPs greater than 220 mm Hg, they state it is reasonable to lower the BP using continuous infusion of antihypertensive medications in closely monitored patients. The 2017 ACC/AHA hypertension guideline warns that for patients presenting with SBP of 150 to 220 mm Hg, acute BP lowering to a goal SBP of less than 140 mm Hg within 6 hours is not beneficial and may potentially cause harm.[1] For those presenting with an SBP greater than 220 mm Hg, the hypertension guideline states it is reasonable to lower BP with a continuous infusion of antihypertensive medications. The National Institute for Health Care and Excellence in the United Kingdom recommends a goal SBP goal of 130 to 140 mm Hg for patients with an ICH presenting within six hours, including patients presenting with SBP greater than 220 mm Hg, provided no contraindications are present.[32]

While the debate continues concerning the optimal BP goal in patients with acute ICH, the important take-home point is that patients should be closely monitored for any signs of ischemia during acute BP lowering. To minimize BP fluctuations, infusions of nicardipine or clevidipine could be considered first-line agents for acute BP control. Enteral antihypertensives can be started as soon as there is access and should be titrated as tolerated for long-term BP control. Sodium nitroprusside is generally avoided in patients with ICH, secondary to the risk for elevations in intracranial pressure due to extravasated intracranial blood and the concern over the medication itself causing elevations in intracranial pressure.

Acute Ischemic Stroke

Acute BP management during an acute ischemic stroke is a balance between preserving cerebral perfusion and minimizing the risk of intracerebral hemorrhage via hemorrhagic conversion of stroke infarcts, especially for those patients who are candidates for fibrinolytic therapy (eg, alteplase). In the stroke penumbra, the area surrounding the infarcted brain tissue, autoregulation is dysfunctional, and cerebral perfusion pressure is more directly related to BP values.[1] Aggressive BP lowering can, therefore, decrease perfusion, causing further ischemia. However, uncontrolled BP may pose a risk of hemorrhagic conversion of the ischemic stroke.

The decision to administer reperfusion therapy is the critical junction in the pathway for determining BP goals during acute ischemic stroke. If patients are not candidates for reperfusion therapy, decreasing BP by 15% is considered reasonable if the BP is greater than or equal to 220/120 mm Hg.[35] However, for patients who are candidates for IV alteplase, the AHA/ASA guideline recommends that the BP be controlled to less than 185/110 mm Hg before administering IV alteplase.[35] During alteplase infusions, the guideline recommends maintaining BP at less than or equal to 180/105 mm Hg.[35] It is essential to monitor BP carefully during alteplase infusions and for 24 hours after completing the infusion. BP elevations above the guideline-specific ranges are thought to increase the risk of cerebral bleeding associated with alteplase administration. Readers are encouraged to visit Chapter 39, “Stroke,” for more details regarding monitoring patients receiving IV alteplase for acute ischemic stroke.

Careful selection and dosing of the appropriate antihypertensive medication is important to maintain the balance of perfusion and BP control. In patients without contraindications, as-needed IV bolus doses of labetalol or continuous infusions of nicardipine or clevidipine are the medications of choice for acute BP control.[35] Intermittent IV boluses of hydralazine or enalaprilat are alternatives that may also be considered.[35]

Hypertensive Encephalopathy

When evaluating patients for hypertensive encephalopathy, clinicians must assure that the symptoms are not attributable to an intracerebral hemorrhage, ischemic stroke, or some other intracranial or vascular pathology (eg, aortic dissection). These conditions may alter the more conservative BP goals recommended for patients with hypertensive encephalopathy. Therefore, the decision to treat a patient for hypertensive encephalopathy is usually based on their symptoms after other neurological conditions have been excluded. Carefully monitored reduction in BP can reverse symptoms while minimizing the risk of ischemic complications. While randomized controlled trials evaluating BP management in hypertensive encephalopathy are lacking, a decrease in BP of not more than 25% in the first hour is reasonable.[52] IV infusions of nicardipine and clevidipine are commonly used as initial therapy.

Acute Coronary Syndromes (ACS)

When a patient with hypertensive crisis presents with an ACS, rapid BP lowering is indicated to lessen cardiac ischemia. When managing hypertensive emergencies in the setting of an ACS, nitroglycerin is a first-line medication due to its ability to cause smooth muscle relaxation and coronary artery dilation. Additionally, nitroglycerin provides symptomatic relief of accompanying chest pain or discomfort. β-blockers are also indicated in all patients with ACS in the absence of contraindications. IV β-blockers are recommended in patients with ACS and tachyarrhythmias or uncontrolled hypertension. In patients with evidence of or who are at risk for developing cardiogenic shock, β-blocker use should be deferred. CCBs such as nicardipine or clevidipine may be used cautiously, taking care to avoid rebound tachycardia, which could increase myocardial oxygen demand and worsen ischemia.[42,53] Sodium nitroprusside is associated with increased mortality in patients with acute myocardial infarction complicated by left ventricular heart failure, presumably due to coronary steal, and should be avoided in this setting.[54] Refer to Chapter 34, “Acute Coronary Syndromes,” for information on the management of patients with ACS.

Acute Decompensated Heart Failure (ADHF) with Pulmonary Edema

Patients with acute pulmonary edema and severe elevations in BP (often referred to as “flash pulmonary edema”) can present with respiratory distress and hypoxemia due to fluid overload. Because acute cardiogenic pulmonary edema is often associated with excessive increases in afterload, afterload reduction is a mainstay of therapy. To achieve afterload reduction, IV antihypertensives should be titrated to a BP reduction of about 25% in the first hour.[1]

Nitroglycerin is a treatment of choice for BP reduction in the setting of ADHF with pulmonary edema.[55] Nitroglycerin causes venous dilation at low doses (≤60 mcg/min) and arterial vasodilation at higher doses (>60 mcg/min).[56] Since nitroprusside is both a potent arterial and venous vasodilator, it is a good option for patients who display an inadequate response to nitroglycerin.[57] An IV loop diuretic such as furosemide should also be administered as soon as possible to help manage fluid overload. Early use (within 60 minutes of presentation to the emergency department) of IV diuretics has been associated with improvements in oxygenation and in-hospital mortality for patients with ADHF.[58] Refer to Chapter 37, "Acute Decompensated Heart Failure," for more details on the management of ADHF.

Aortic Dissection

Aortic dissections are worsened by aortic wall stress. BP, heart rate, and the velocity of ventricular contraction all contribute to aortic wall stress. β-blockers are first-line to minimize wall stress by controlling all three contributing factors. It is crucial to control heart rate first, as vasodilatory IV antihypertensives may lead to reflex tachycardia, worsening aortic wall stress. Because aortic dissection can rapidly lead to decompensation and death, heart rate should be reduced to and maintained at less than 60 beats per minute (bpm), and SBP lowered to less than 120 mm Hg. Ideally, achievement of both heart rate and BP goals should occur within 20 minutes, which is notably more aggressive than with other types of target organ damage.

The choice of β-blocker depends on patient-specific factors. In a patient who might be expected to have an intolerance to a β-blocker, such as those with heart failure or asthma, esmolol should be considered due to its short half-life. Labetalol possesses both α- and β-blocking properties and may be more effective in achieving heart rate and BP goals in patients with aortic dissection. However, the longer half-life of labetalol is a disadvantage because it cannot be titrated as easily as esmolol. Other parenteral pharmacotherapy options include metoprolol and propranolol.[34] These medications also have long half-lives and, therefore, should not be administered via continuous infusion.

Once the heart rate goal is achieved, an additional IV antihypertensive from an alternative class may be utilized in combination with the β-blocker if BP remains above goal. An IV vasodilator such as sodium nitroprusside or nicardipine would be appropriate add-on therapy.[34]

Supportive therapies depend on the severity of the aortic dissection. Dissections in the ascending aorta (type A dissections) are considered surgical emergencies. Type B dissections, or descending aortic dissections, may be managed medically or surgically depending on the severity. Because pain may contribute to tachycardia and hypertension, adequate analgesia is crucial for patients with aortic dissection.[34]

Acute Kidney Injury

Patients with acute kidney injury due to hypertensive crisis require BP lowering of about 25% in the first hour. Because of this, medications that may cause precipitous BP drops or worsen kidney perfusion should be avoided.[1] In a hypertensive emergency with acute kidney injury, DHP CCBs should be considered first. Although labetalol is not nephrotoxic, it was associated with greater BP variation than nicardipine in multiple studies.[59] An alternative option for the management of hypertension-associated acute kidney injury is fenoldopam. Fenoldopam has renoprotective effects that may reduce the risk of requiring renal replacement therapy.[37] ACE inhibitors such as enalaprilat should be avoided in the setting of hypertensive acute kidney injury due to the potential to worsen kidney function.

Severe Hypertension in Pregnancy

Due to the high risk associated with pre-eclampsia and eclampsia, treatment with IV antihypertensive therapy should be initiated within 30 to 60 minutes or as soon as possible to target an SBP less than 140 mm Hg. First-line agents include IV hydralazine or IV labetalol. The American College of Obstetricians and Gynecologists guideline suggests that oral IR nifedipine may also be used for this indication. However, IR nifedipine has largely fallen out of favor due to increased rates of severe adverse drug reactions and the risk of myocardial ischemia.[21] If used to treat hypertensive crisis during pregnancy, IR nifedipine should be reserved as a third-line agent.

In patients with pre-eclampsia with severe features, seizure prophylaxis with magnesium sulfate is indicated. Magnesium is the medication of choice for preventing eclampsia, which is the convulsive presentation of gestational hypertension. Magnesium is administered as a bolus dose of 4 to 6 grams over 15 to 30 minutes at the onset of labor, followed by a 1- to 2-gram per hour continuous infusion for at least 24 hours after delivery. Close laboratory, cardiac, and respiratory monitoring is required to ensure that the patient is not experiencing magnesium toxicity.[21]

Pheochromocytoma Crisis

The treatment of choice for pheochromocytoma crisis is α-adrenergic blockade with phenoxybenzamine or doxazosin. These medications are utilized temporarily until surgical resection of the tumor can occur. It is not recommended to use β-blockers until adequate β-blockade can be achieved. Without α-blocking medications, β-blockade can cause unopposed α-receptor stimulation, increasing vasoconstriction and worsening the hypertensive crisis. However, once treatment is initiated with an α-receptor antagonist, tachycardia can be further managed with a β-blocker. If an additional agent is needed to control BP, CCBs or metyrosine (catecholamine synthesis inhibitor) may be used.[60]

Transitioning from IV to Oral

After patients with a hypertensive emergency are stabilized on an IV antihypertensive regimen, transition to oral antihypertensives should be considered. Ideally, patients should be started on an agent with which they can be maintained long term. Before this transition is made, it should be confirmed that target organ damage is no longer worsening and that it is appropriate and safe to utilize the patient's gastrointestinal tract. Additionally, BP should be at or near the recommended goal depending on the underlying organ dysfunction for at least two consecutive readings before the transition is made.[61]

Choice of oral antihypertensive should follow evidence-based guidelines and patient-specific factors (Chapter 30, "Hypertension"). IV therapy should be continued while oral therapy is started in a stepwise fashion. If a patient has a home antihypertensive regimen, this should be resumed or intensified. Individual oral antihypertensive pharmacokinetic properties should be considered when determining how rapid titrations can be made. Quick but safe transitions from IV to oral antihypertensive therapy can reduce ICU and hospital length of stay and reduce healthcare costs.[62]

EVALUATION OF THERAPEUTIC OUTCOMES

Patients being managed with IV antihypertensives should have BP checked at least every 15 minutes while medication doses are titrated. Some patients may require more frequent monitoring depending on the clinical status and medication being used. Once a stable dose has been reached, BP readings may be performed every 1 hour. While not required, many patients with a hypertensive emergency will have continuous BP monitoring performed via an arterial line placement.

Laboratory monitoring during treatment of hypertensive emergency is dependent upon the type of target organ dysfunction present and the antihypertensive regimen used. If the emergency involves bleeding into a critical organ site (eg, aortic dissection), complete blood counts should be monitored to follow hemoglobin and hematocrit concentrations trends. In addition, a comprehensive metabolic panel should be obtained to assess for kidney or hepatic injury and electrolyte disturbances. Triglyceride levels may be warranted in patients on prolonged infusions of clevidipine.

Repeated symptomatic and diagnostic assessments are also important. Physical exams should be repeated regularly during hospitalization to monitor for new, worsening, or the resolution of symptoms specific to the affected target organ systems. Repeat diagnostic imaging may also be required depending on the type of target organ dysfunction identified (eg, ICH).

CONCLUSION

Treating patients with hypertensive crises is complex and requires a detailed evaluation of symptoms, history (medical, medication, and dietary), and careful measurement of BP. In patients without evidence of target organ damage (hypertensive urgency), conservative management (eg, resumption of or adjustments to chronic antihypertensive therapy) is often sufficient. Patients with evidence of target organ damage (hypertensive emergency) must be treated as a medical emergency. Prompt identification of target organ damage and treatment to patient-specific goals can prevent adverse effects of tissue ischemia and progressive target organ damage. Careful consideration to the diagnosis of target organ damage is necessary when treating patients with hypertensive crisis. Once target organ damage is identified, clinicians should utilize patient-specific factors and guideline-recommended BP goals to outline acute treatment plans and select the appropriate antihypertensive treatment. Clinicians should familiarize themselves with the contraindications and adverse effect profiles of available antihypertensive medications to ease management decisions. IV infusions of antihypertensives are generally preferred, but other routes may be considered in specific circumstances. Initial dosing and dose titrations are also key to patient management. Lastly, treatment plans do not end with the selection and initiation of appropriate pharmacotherapy. Frequent monitoring of BP and the clinical and laboratory markers of target organ damage is important to minimize adverse events and document clinical success.

Achievement of treatment goals is best when patients are cared for by interprofessional care teams, in which all members contribute their expertise.

SELF-ASSESSMENT QUESTIONS

Use the following scenario to answer questions 1 to 3:

A 72-year-old female presents to the emergency department with complaints of shortness of breath. Blood pressure is 234/116 mm Hg. A chest x-ray reveals bilateral diffuse hazy infiltrates. Past medical history includes coronary artery disease, heart failure, hypertension, and osteoporosis. Home medications include alendronate 70 mg once weekly, aspirin 81 mg daily, furosemide 20 mg twice daily, losartan 100 mg daily, metoprolol XL 100 mg daily, and rosuvastatin 40 mg daily. The patient reports consuming a significant amount of fried and salty foods while attending a barbeque.

1. How should this patient’s hypertension be classified?

    A. Prehypertension

    B. Stage 1 hypertension

    C. Hypertensive urgency

    D. Hypertensive emergency

2. Which of the following blood pressure targets is the *most appropriate* for this patient?

    A. 25% reduction over the first hour then 160/100 to 110 mm Hg over the next 2 to 6 hours.

    B. 50% reduction over the first hour then 140/100 to 110 mm Hg over the next 2 to 6 hours.

    C. Immediately decrease the blood pressure to a goal of <140/90 mm Hg within 1 hour.

    D. Immediately decrease the blood pressure to a goal of <120/80 mm Hg within 1 hour <140/90 mm Hg as soon as possible.

3. In addition to IV furosemide, which of the following represents the *best* medication regimen to manage this patient’s acute hypertension?

    A. Enalaprilat 5 mg IV push

    B. Hydralazine 20 mg IV push

    C. Labetalol 1 mg/min IV infusion

    D. Nitroglycerin 10 mcg/min IV infusion

Use the following scenario to answer questions 4 to 6:

A 68-year-old male presents to the emergency department with slurred speech, facial droop, and an unsteady gait. The patient’s wife reports the patient was in a normal state of health 2.5 hours ago. Blood pressure readings upon arrival were 196/92 mm Hg and 204/96 mm Hg. Heart rate is 89 bpm. Upon evaluation by the interdisciplinary healthcare team, the patient is diagnosed with ischemic stroke and a decision is made to administer IV alteplase.

4. Which of the following is the *most appropriate* blood pressure target for this patient?

    A. <140/80 mm Hg

    B. <180/105 mm Hg

    C. A 25% reduction in 1 hour

    D. A 50% reduction in 1 hour

5. Which of the following is the *most appropriate* antihypertensive regimen for this patient?

    A. Metoprolol 5 mg IV push

    B. Hydralazine 10 mg IV push

    C. Nicardipine 5 mg/hr IV infusion

    D. Nitroglycerin 5 mcg/min IV infusion

6. Which of the following the *best* represents the risk of rapidly reducing blood pressure in this patient?

    A. Cerebral ischemia

    B. Cerebral hemorrhage

    C. Acute kidney injury

    D. Coronary ischemia

Use the following scenario to answer questions 7 to 9:

A 45-year-old male presents from the primary care physician's office for management of elevated blood pressure. The patient reports having no symptoms and was at the physician's office for a routine physical. Blood pressure in the office was 204/120 mm Hg. As a result, the patient was instructed to immediately report to the emergency department. Blood pressure in the ED is 198/116 mm Hg. Past medical history includes gout and hypertension. Home medications include allopurinol 100 mg daily, amlodipine 10 mg daily, carvedilol 25 mg twice daily, and lisinopril/hydrochlorothiazide 40/25 mg daily but the patient reports running out of medications 4 days ago. The patient also takes acetaminophen occasionally for headaches (about twice monthly).

7. How should this patient's hypertension be classified?

    A. Prehypertensive

    B. Stage 1 hypertension

    C. Hypertensive urgency

    D. Hypertensive emergency

8. Which of the following is the *best* strategy for managing this patient's blood pressure?

    A. Start nicardipine 5 mg/hr IV infusion

    B. Administer clonidine 0.1 mg PO as needed

    C. Administer labetalol 10 mg IV push

    D. Reinitiate home antihypertensives as reported

9. Which if the following is the *most likely cause* for this patient's visit to the emergency department?

    A. Hypertensive emergency at the doctor's office

    B. Interruption of home BP medication regimen

    C. Elevated BP from painful gout attack

    D. Suboptimal doses of antihypertensive medications

Use the following scenario to answer questions 10 to 11:

An 82-year-old male presents with "tearing pain" located in the chest and back. Blood pressure is 182/90 mm Hg and heart rate is 96 beats per minute. A CT scan of the chest reveals a Type B descending aortic dissection. The patient does not report taking any medications at home and does not regularly seek medical care.

10. Which of the following medications can safely be initiated first in this patient?

A. Clevidipine

B. Esmolol

C. Nicardipine

D. Nitroprusside

11. Which of the following best represents clinical goals to prevent additional organ damage in this patient?

A. SBP < 120 mm Hg

B. SBP < 140 mm Hg

C. SBP < 120 mm Hg and HR < 60 bpm

D. SBP < 140 mm Hg and HR < 60 bpm

12. Which of the following physical exam findings are characteristic of aortic dissection?

A. Discordant blood pressure readings on opposite arms

B. Peripheral pitting edema palpated in the lower extremities

C. Papillary edema visualized fundoscopically in both eyes

D. Jugular venous distension was observed unilaterally

Use the following scenario to answer questions 13 to 15:

A 53-year-old female presents to the primary care physician for a checkup and to request medication refills. Home medications include nifedipine XR 30 mg daily, hydrochlorothiazide 12.5 mg daily, valsartan 40 mg daily, ibuprofen 600 mg twice daily as needed for back pain, and metformin 500 mg twice daily. The patient reports adherence with home medications and enjoys drinking multiple sports drinks while playing racquetball. Blood pressure is 188/114 mm Hg. When checked 10 minutes later, blood pressure is 194/112 mm Hg and heart rate is 62 bpm. The patient reports that blood pressure at home is typically about 170/90 mm Hg.

13. Which of the following best represents how this patient’s autoregulation curve could be altered due to long-standing uncontrolled hypertension?

A. Shifted to the right which increased the risk of tissue ischemia with acute BP lowering

B. Shifted to the right which increased the risk of cerebral edema with acute BP lowering

C. Shifted to the left which increased the risk of tissue ischemia with acute BP lowering

D. Shifted to the left which increased the risk of cerebral edema with acute BP lowering

14. Which of the following is the *most appropriate* pharmacologic recommendation now?

A. Change nifedipine to equipotent dose of amlodipine

B. Administer IV labetalol now as a one-time injection

C. Change hydrochlorothiazide to furosemide

D. Increase the dose of nifedipine

15. Which of the following counseling points would be *most appropriate* for this patient during this office visit?

A. Avoid excessive physical exertion to prevent further blood pressure elevations

B. Avoid the use of nonprescription medications such as NSAIDs and certain herbal supplements

C. Report to the emergency department for evaluation of extremely elevated blood pressure

D. Limit water and sports drinks intake during periods of intense exercise

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** This patient's hypertension can currently be classified as a hypertensive emergency (see "Hypertensive Emergency" section). The patient has acutely elevated blood pressure >180/120 mm Hg with evidence of target end-organ damage. She is experiencing shortness of breath and her chest radiograph shows evidence of fluid overload. This is indicative of acute heart failure which is a type of target end-organ damage.

2. **A.** A 25% blood pressure reduction over the first hour then to 160/100 to 110 mm Hg over the next 2 to 6 hours is recommended to alleviate target end-organ dysfunction while minimizing precipitous blood pressure decreases that could precipitate ischemic complications (see Table e31-2). Alleviation of acute heart failure will prevent the worsening of acute respiratory insufficiency.

3. **D.** Nitroglycerin 10 mcg/min IV infusion would be the most appropriate choice for this patient because the vasodilatory properties of nitroglycerin in combination with the diuretic effect of furosemide will help to decrease pulmonary edema and reduce blood pressure (see Table e31-3). In the setting of acute heart failure, β-blockers such as labetalol should be avoided due to negative inotropic effects that could worsen cardiac output. Hydralazine and enalaprilat should not be used first-line given the unpredictable pharmacodynamic effects and relatively slow onsets of action.

4. **B.** The blood pressure target for patients who are candidates for fibrinolytic therapy (eg, alteplase) is <180/105 mm Hg to minimize the risk of hemorrhagic conversion of ischemic stroke (see Table e31-2). It is not recommended to target goals lower than 180/105 due to the risk of worsening cerebral ischemia.

5. **C.** Nicardipine 5 mg/hr IV infusion is the most appropriate choice for this patient given its ease of titration and predictable pharmacokinetics (see Table e31-3). Nitroglycerin is preferred in patients with cardiac-related target end-organ dysfunction, which is not relevant in this patient. Hydralazine's unpredictable onset and pharmacodynamic effects render it suboptimal for a patient who requires rapid blood pressure control and avoidance of precipitous blood pressure decreases. Metoprolol, while it may have some effect on blood pressure, primarily acts as an agent to reduce heart rate which is not the primary goal in this patient.

6. **A.** Risk of blood pressure decreases that are too rapid include worsening tissue ischemia (see Fig. e31-1). This is especially problematic in the setting of ischemic stroke, where brain perfusion is crucial. Hemorrhagic conversion would be a concern in the setting of uncontrolled hypertension rather than decreased blood pressure. Acute kidney injury and coronary ischemia are both general risks of rapidly lowering blood pressure. However, in the setting of acute ischemic stroke, the risk of cerebral ischemia would be most concerning.

7. **C.** This patient's blood pressure should be classified as hypertensive urgency (see "Hypertensive Urgency" section). He presents with acute elevations >180/120 mm Hg confirmed on multiple readings. However, this patient is asymptomatic with no evidence of target end-organ damage. Therefore, this cannot be classified as an hypertensive emergency.

8. **D.** Because this patient has hypertensive urgency, he should be managed conservatively by reinitiating his home antihypertensives (see "Treatment Hypertensive Urgency" section). He reports running out of medications 4 days prior which could have led to his hypertensive urgency. The patient's medications should be renewed, and he should be counseled on the importance of adherence to the prescribed regimen.

9. **B.** This patient reports running out of medications 4 days prior which could have led to his hypertensive urgency (see Table e31-1). The patient's medications should be renewed, and he should be counseled on the importance of adherence to the prescribed regimen. If blood pressures remain uncontrolled upon the next office visit, then his regimen should be modified accordingly.

10. **B.** Esmolol should be used first-line in this patient due to the presence of aortic dissection (see "Recommendations for Specific Target Organ Damage" section). Patients with aortic dissection must be treated with a rate-controlling medication prior to the use of a medication that causes vasodilation to prevent the risk of rebound tachycardia. Tachycardia must be avoided to minimize shear stress on the damaged aortic wall.

11. **C.** When managing aortic dissection, it is recommended to both treat blood pressure (SBP < 120 mm Hg) and control the heart rate (HR goal < 60 beats/min) within 20 minutes to prevent further organ damage (see Table e31-2).

12. **A.** Discordant blood pressure readings on opposite arms is a characteristic physical exam finding in patients with aortic dissection. Peripheral pitting edema and jugular venous distension would be expected to occur more frequently in the setting of cardiac failure and fluid overload. Papillary edema would be expected to occur in the setting of hypertensive acute retinopathy. (See "Clinical Presentation Blood Pressure Assessment" section.)

13. **A.** As a result of long-standing uncontrolled hypertension, the patient's autoregulation curve is most likely shifted to the right (see Fig. e31-1). This alteration in autoregulation increased the risk of tissue ischemia with acute decrease in BP despite BP readings being in the otherwise "normal" range. The curve is not generally shifted to the left in patients with long-standing hypertension.

14. **D.** Increasing the dose of one of her antihypertensive medications would be the best course of action in this patient (see "Hypertensive Urgency" in "Treatment" section). None of her antihypertensives (nifedipine XR, hydrochlorothiazide, or valsartan) are currently prescribed at optimized doses and could potentially provide better control of her hypertension if increased. It would not be appropriate to switch the patient to a different medication in the same class if the patient is tolerating the medication well. There is no need to add on an additional agent since she is already on three guideline-recommended medications. IV therapy is not an appropriate management strategy for hypertensive urgency.

15. **B.** Avoidance of the use of certain nonprescription medications such as NSAIDs or certain herbal supplements would be an appropriate counseling point in any patient with hypertension but is especially important in the setting of uncontrolled hypertension (see Table e31-1). Avoiding physical exertion or drinking water are not appropriate interventions for this patient. This patient should not report to the emergency department given that there is no suspicion for target end-organ damage.

Chapter e35: Peripheral Arterial Disease

Kristin Watson; Sarah Anderson

KEY CONCEPTS

KEY CONCEPTS

1. Peripheral arterial disease (PAD) is a form of atherosclerotic cardiovascular disease (ASCVD) that occurs in the peripheral arteries. Lower extremity PAD is the most common form of PAD.

2. Lower extremity PAD is associated with an increased risk of limb loss and death.

3. The most prevalent PAD risk factors are tobacco smoking, diabetes mellitus (DM), hypertension, and dyslipidemia. The risk of developing PAD increases with age.

4. Symptoms of lower extremity PAD may include cramping or discomfort in the affected lower extremity(ies). A significant portion of those with PAD will be asymptomatic. Signs of lower extremity PAD include, but are not limited to, diminished or absent pedal pulses, nonhealing wounds, brittle and hypertrophic toenails, and/or cool skin. The presence of signs and/or symptoms in those at risk for PAD should prompt further evaluation.

5. The ankle-brachial index (ABI) is the most common test used to diagnose lower extremity PAD. PAD is defined by an ABI score ≤ 0.9 for one or more of the pedal pulses (ie, dorsalis pedis, posterior tibial). A score > 1.4 is indicative of noncompressible arteries which may be present in those with DM and/or chronic kidney disease (CKD).

6. ASCVD risk reduction is prudent to lower the risk of cardiovascular (CV) complications associated with PAD. This includes glycemic and blood pressure (BP) control. A high-intensity statin is recommended to reduce the risk of CV and limb-related events. Smoking cessation has been shown to reduce the risk of limb loss and death.

7. Participation in a structured exercise training program has been shown to improve functional status and quality of life and to decrease lower extremity symptoms.

8. Revascularization is a potential therapeutic option for patients who have persistent lower extremity PAD symptoms despite pharmacological therapy, exercise, and smoking cessation.

9. Low-dose aspirin or clopidogrel is recommended for those with symptomatic lower extremity PAD to lower the risk of CV events and death.

10. An antithrombotic regimen is prescribed after revascularization to lower the risk of CV events and limb-related events. Options include aspirin or clopidogrel monotherapy, dual antiplatelet therapy with aspirin and clopidogrel, or rivaroxaban 2.5 mg twice daily combined with low-dose aspirin.

11. Cilostazol can be considered in those with lower extremity PAD symptoms despite other pharmacological therapy, exercise, and smoking cessation. This agent is not to be used in those with heart failure owing to an increased risk of death.

INTRODUCTION

① Peripheral arterial disease (PAD) is characterized by atherosclerosis of the peripheral arteries. Lower extremity PAD specifically refers to atherosclerotic disease from the aortoiliac segments to the pedal arteries.[1] While PAD can occur in several peripheral arteries, this chapter will focus predominantly on the treatment of lower extremity PAD because it is most common. The atherosclerotic process leads to the accumulation of plaque material within the arterial wall, narrowing the lumen and reducing blood flow to the lower extremities. Risk factors for PAD are similar to those for atherosclerosis in other parts of the body and include age ≥ 65 years old, tobacco smoking, diabetes mellitus (DM), hypertension (HTN), and dyslipidemia.[2,3] Presence of PAD is associated with a high risk of morbidity and mortality; those with PAD have a threefold increased risk of all-cause mortality compared to those without the disease.[2,3] Because of its associated cardiovascular (CV) morbidity and mortality, PAD is a marker for atherosclerotic cardiovascular disease (ASCVD) that requires multiple interventions aimed at lowering risk.[4] The treatment of lower extremity PAD focuses on minimizing and managing risk factors, alleviating symptoms, and reducing cardiovascular disease (CVD) progression through nonpharmacologic and pharmacologic therapy.[3,4]

EPIDEMIOLOGY

Lower extremity PAD, defined as an ankle-brachial index (ABI) ≤0.9, is present in as many as 6.5 million US adults ≥ 40 years old.[1,3,4] More than 202 million people worldwide are affected by PAD.[1,4] In the United States, prevalence estimates may be higher as published information does not include recent data obtained during the current DM and obesity epidemics.[1] Between 2000 and 2010, the incidence of PAD increased by 13.1% in high-income countries and by 28.7% in low-income countries.[5] ② Up to 1.3% of patients with lower extremity PAD experience chronic limb-threatening ischemia (CLTI), which can be attributed to either luminal narrowing or atherothrombosis, often leading to above- and below-the-knee amputations.[4,6,7] CLTI is defined as two or more weeks with ischemic rest pain, non-healing wounds or ulcers, or gangrene.[3] The global mortality rates attributable to PAD are 45.4% for males and 54.6% for females.[4] Taken together, these data represent a global public health concern and burden, given the increasing incidence in all countries and the close link between PAD and CV morbidity and mortality.

③ The incidence of PAD increases with increasing age, with an approximate doubling per decade of life beginning with age 40.[4] Males and females are similarly affected by PAD, with prevalence varying by age and race/ethnicity within each sex category (Fig. e35-1).[4] Prevalence of PAD is greater in Black persons compared to non-Hispanic White persons, particularly after the age of 50 years in males and after the age of 60 years in females.[8] Lower income and lower educational attainment are associated with increased prevalence of PAD while lower socioeconomic status and Black race are associated with greater risk of amputation related to PAD.[9–11]

With respect to lifestyle choices, being a current or former tobacco smoker is the risk factor most strongly associated with PAD, with current tobacco smokers having the highest risk.[5,12,13] Current or prior tobacco smoking also contributes to disease progression.[4,5,14] Comorbidities also confer risk of PAD. The presence of DM increases the risk of PAD by 30% to 80%.[5,12] HTN is similarly associated with a 50% increase odds of developing PAD; each 20 mm Hg increase in systolic blood pressure (SBP) increases the risk of PAD by up to 32%.[5,12] Dyslipidemia, defined as total cholesterol (TC) > 200 mg/dL (5.17 mmol/L), is less strongly associated with PAD; each 39 mg/dL (1.01 mmol/L) increase in TC increases the risk of PAD by 14%.[5,12] As much as 75% of the risk associated with PAD has been attributed to tobacco smoking, type 2 DM (T2DM), HTN, and dyslipidemia.[15] Patients with PAD risk factors should undergo a comprehensive medical history and physical exam annually in an effort to mitigate risk factors and evaluate for the presence of PAD and other forms of ASCVD.[3]

ETIOLOGY

Risk factors for PAD are like those for other atherosclerotic conditions (Clinical Presentation box).[3,5,13] The risk of PAD increases by 50% with one risk factor and more than 10-fold with three or more.[13] A risk assessment tool was created to predict an individual's lifetime risk of developing PAD. This calculator accounts for the presence of atherosclerotic risk factors, race, and sex, and is available at[12]: http://ckdpcrisk.org/padrisk/

Family history and genetics play a role and are independent of atherosclerotic risk factors.[4,16] Elevated homocysteine levels have been associated with an elevated risk of developing atherosclerosis.[17] HTN during pregnancy and sedentary behavior may also contribute to the development of PAD.[4,18] The presence of chronic kidney disease (CKD) is associated with an increased risk of lower extremity PAD and amputation, a complication of PAD.[19] Other predictors for amputation include the severity of PAD, based on the ABI, the severity of symptoms, and DM.[20,21]

PATHOPHYSIOLOGY

In most cases, PAD in the lower extremities is caused by progressive atherosclerosis and impacts medium and large-sized arteries. The iliac, femoral, popliteal, and/or tibial arteries are most involved (Fig. e35-2A).[20–23] Endothelial injury, often at the artery branches, results in the accumulation of plaque in the vessel intima. DM and smoking are examples of factors that can cause damage to the vessel wall. The atherosclerotic plaque that develops is comprised of cholesterol, inflammatory cells, smooth muscle cells, and connective tissue. Decreased nitric oxide (NO) production and increased oxidative stress impair vasodilatory response and increase arterial stiffness.[22,24] These factors lead to chronic occlusion and stenosis within atherosclerotic arteries.[23,25] PAD can form in one or more arteries of one or both legs. Additionally, disease development and progression can vary between each leg.[26]

④ Ischemic symptoms and complications of the lower extremities are common. Walking and other activities involving the legs increase oxygen demand. In the absence of PAD, vasodilation occurs in response to increased oxygen demand permitting perfusion to the muscles and preserving blood flow.[23] In patients with PAD, the increase in demand cannot be met because the atherosclerotic plaque occludes blood flow and impaired vasodilation causes fixed resistance (Fig. e35-3).[23,25] Impaired perfusion of skeletal muscle contributes to pain or discomfort in the affected portion(s) of the leg(s). For example, intermittent claudication (IC) is a common symptom of limb ischemia causing discomfort or cramping of the lower extremities with exertion. Those with impaired flow in the iliac artery may experience buttock pain with exertion (Fig. e35-2A). Decreased blood flow to the skin and subcutaneous tissues can result in CLTI.[3] Nonhealing wounds and amputation are also potential consequences of impaired blood flow and vascular dysfunction in the lower extremities. Importantly, many patients with lower extremity PAD are asymptomatic, typically a result of a sedentary lifestyle.[3,26]

FIGURE e35-3

Hemodynamic alterations in peripheral arterial disease. (*A*) Perfusion through a lower extremity artery without atherosclerotic disease at rest. (*B*) Perfusion during exercise (increase oxygen demand) through a lower extremity artery without atherosclerotic disease. A compliant blood vessel allows for arterial dilation in response to an increase in oxygen demand. There is a balance of oxygen supply and demand. (*C*) Perfusion of a lower extremity artery with PAD at rest. Narrowing of the arterial lumen occurs in those with PAD. (*D*) Perfusion of a lower extremity artery with PAD during exercise. Arterial dilation is unable to appropriately respond to the increased oxygen demand leading to a mismatch of oxygen supply and demand. This is due to the presence of the atherosclerotic lesion(arrows) and impaired endothelial function. PAD, peripheral arterial disease.

There are several possible nonatherosclerotic causes of PAD, including trauma, vasculitis, and thrombosis, among others, but these are uncommon.[22]

This chapter focuses on the management of PAD due to atherosclerosis.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Peripheral Arterial Disease

General

- Patients with PAD are likely to be male, 40 years of age and older, with hypertension, hypercholesterolemia, DM, impaired renal function, presence of CAD or CVD, and/or current or former tobacco smoking.

Signs and Symptoms

- The clinical presentation of lower extremity PAD is variable and includes symptoms ranging from asymptomatic to lower extremity IC and pain. Patients may also present with CLTI, which appears as nonhealing wounds and/or gangrene of the lower extremities in combination with lower extremity pain at rest. Acute limb ischemia, a potentially life-threatening medical emergency, develops over a short period of time (<2 weeks). Patients with acute limb ischemia will have evidence of severe hypoperfusion potentially leading to major tissue loss. Those with more serious cases may have profound muscle paralysis or significant sensory loss.[3]
- IC is generally regarded as the primary symptom indicator in lower extremity PAD. IC has been described as a discomfort, cramping, pain, or numbness in the affected lower extremity(ies) (typically the buttock, thigh, calf, or foot, either singularly or in combination) during physical activity and resolves within 10 minutes of rest. Patients can present with atypical symptoms. For example, some patients may start to develop pain at rest and the pain intensifies with exertion. Functional impairment has been shown to be similar between those with IC, atypical symptoms, and those who do not report symptoms. Therefore, clinicians cannot rely on the presence of symptoms alone when assessing for the presence of PAD.[3,27]
- Physical examination may reveal nonspecific signs of decreased blood flow to the lower extremities (eg, cool, dry skin; cyanosis; bruits; brittle, hypertrophic toenails; muscle atrophy; lack of hair on the calf, feet, and/or toes). Additionally, posterior tibial and/or dorsalis pedis pulse strength may be diminished or pulses absent.[3]

Diagnostic Tests

- There are no laboratory tests specific to PAD.
- Patients with risk factors for or with symptoms and/or physical examination suggestive of lower extremity PAD should undergo ABI testing.[1,3]
  - Risk Factors for PAD[3,14]
    - Known atherosclerosis in another vascular bed (eg, carotid, coronary, renal)
    - Age 65 or older
    - Age 50 to 64 with atherosclerosis risk factors, including DM, hypertension, dyslipidemia, current or prior tobacco smoking; and/or family history of PAD
    - Age less than 50 with DM and at least one additional risk factor for atherosclerosis
- The ABI is a noninvasive, quantitative test that is highly sensitive and specific (≥90%) for diagnosing lower extremity PAD.

ABI, ankle-brachial index; CAD, coronary artery disease; CLTI, chronic limb-threatening ischemia; CVD, cardiovascular disease; DM, diabetes mellitus; IC, intermittent claudication; PAD, peripheral arterial disease.

An important component of PAD assessment is obtaining a thorough patient history of both symptoms and prior diagnoses of atherosclerosis and/or known atherosclerotic risk factors (eg, HTN, dyslipidemia, DM, tobacco smoking). However, sole reliance on patient history will miss up to 90% of patients with lower extremity PAD.[28,29] PAD symptoms gradually worsen over time, making it challenging for clinicians and patients to identify changes that may occur.[1] Therefore, a physical examination of the patient is a key component of the assessment process (refer to Beyond the Book for a link to a video describing this in more detail). Evaluation of the lower extremities may reveal nonspecific signs of decreased blood flow to the extremities (eg, cool, dry skin; cyanosis; bruits; brittle, hypertrophic toenails; muscle atrophy; lack of hair on the calf, feet, and/or toes) or, in severe cases, nonhealing ulcers or gangrene may be present.[30] Care should be taken to exclude other conditions (eg, peripheral neuropathy, deep vein thrombosis) that possess similar signs and symptoms. Those with signs and/or symptoms of PAD should undergo diagnostic testing.

⑤ The ABI is a noninvasive, quantitative test that is a highly sensitive and specific (≥90%) tool in the diagnosis of lower extremity PAD.[3] To perform an ABI measurement, the patient should first rest in the supine position for 15 to 30 minutes. Then, in this position, the SBP is measured at the brachial arteries on both arms and the dorsalis pedis and posterior tibial arteries of the legs with a standard sphygmomanometer and a hand-held doppler (Fig. e35-2B).[3] The higher pressure obtained at the ankle arteries is divided by the higher measurement taken at the brachial arteries; thus, the ABI is the ratio of the higher ankle SBP divided by the higher brachial SBP.[14] An alternative method for screening uses the lower (rather than the higher) of the two ankle pressures as the numerator in the calculation.[31] Interpretation of the results are presented in Table e35-1. The ABI measurement can be a strong predictor of future atherosclerotic CV morbidity and mortality associated with PAD; patients with an ABI < 0.3 are at a significantly high risk of such events.[32]

TABLE e35-1

Ankle-Brachial Index Interpretation

Ankle-Brachial Index Score	Classification
>1.4	Noncompressible arteries may be present in those with diabetes
1-1.4	Normal
0.91-0.99	Borderline
≤0.9	PAD
0.7-0.9	Mild PAD
0.4-0.7	Moderate PAD
<0.4	Severe PAD

PAD, peripheral arterial disease.

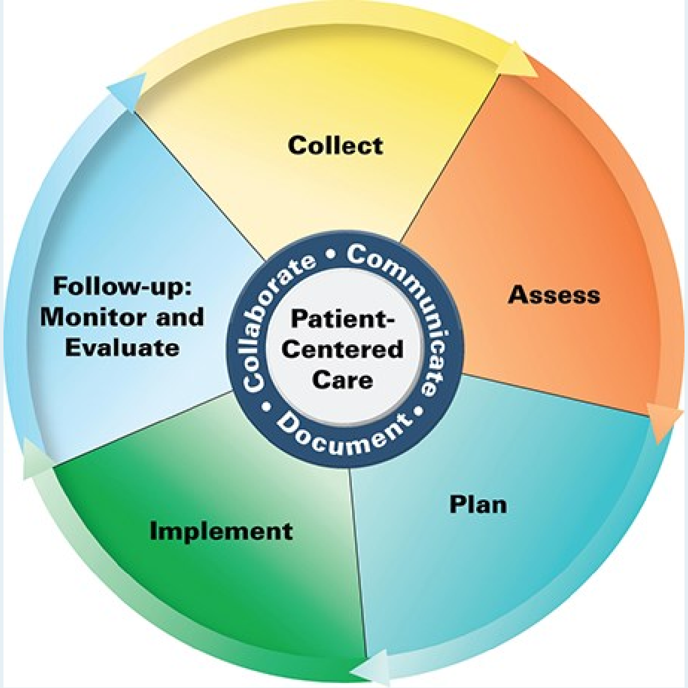
Data from Reference 3.

An ABI of >1.40 is consistent with noncompressible arteries, typically observed in those with DM and/or CKD.[1] If PAD is still suspected in a patient with an ABI >1.40, a toe-brachial index (TBI) can be used instead to confirm the diagnosis. This is because toes are rarely affected by calcification.[1] Similarly, in a patient with a normal or borderline ABI (>0.90 to ≤ 1.40) who is experiencing PAD-like symptoms, exercise treadmill ABI testing should be used to determine if PAD is present.[3,33] Patients with lower extremity PAD will demonstrate a significant drop in the ABI after exercise, but their pain remains normal or unchanged unless IC is present. When a patient is not found to have PAD with symptoms suggestive of the disease, alternative diagnoses (eg, nerve root compression) should be considered.[34,35]

Other noninvasive tools are available for the diagnosis of PAD, including duplex ultrasound, magnetic resonance angiography (MRA), and computed tomographic angiography (CTA). However, an ABI is a sufficient means of diagnosis and arteriography is not necessary or encouraged except in situations such as planned surgical revascularization where it can aid in further visualization of the affected vasculature.[3,36]

PATIENT CARE PROCESS

Patient Care Process for Peripheral Arterial Disease



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, past medical history)
- Healthcare and prescription insurance status
- Social history (eg, tobacco smoking status, physical activity habits)
- All current prescription medications and over-the-counter products
- Medication intolerances (eg, prior bleeding with antiplatelet) and allergies
- Objective data:
    - Left and right brachial blood pressures
    - Left and right dorsalis pedis blood pressures
    - Left and right posterior tibial blood pressures
    - Physical examination findings of lower extremities (document: strength or absence of peripheral pulses; temperature; presence or absence of bruits, muscle atrophy, pallor, cyanosis, ulcers, non-healing wounds, and/or gangrene)
    - Walking assessment, including pain-free walking and maximum walking distances
    - Baseline laboratory parameters (eg, basic metabolic panel, lipid panel, hemoglobin A1C)

Assess

- ABI for left and right legs (see Table e35-1, Fig. 35-2B)
- Quality of life related to limitations in mobility
- Control of ASCVD risk factors (ie, hypertension, DM, dyslipidemia, and tobacco smoking)
- Physical and financial ability to participate in a supervised or structured exercise program (see Table e35-2)
- Presence of contraindications to antithrombotic and/or anticlaudication therapies (see Table e35-5)

Plan*

- Drug therapy regimen, including antithrombotic therapy and anticlaudication therapy (for each: brand and generic name, dose, route and frequency of administration, and duration of therapy), when appropriate (see Tables e35-3, e35-4, and e35-5)
- Risk factor modification to achieve goals (eg, BP, glucose, lipids) and tobacco smoking cessation (see Table e35-3)
- Monitoring (including self-monitoring) parameters of efficacy (eg, claudication pain, quality of life) and safety (eg, signs and symptoms of bleeding); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, physical activity recommendations)
- Referrals to other providers when appropriate (eg, vascular specialist, physical therapist)

Implement*

- Provide patient education regarding all elements of the pharmacotherapy and nonpharmacotherapy treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, walking assessment) within 1 to 3 months

Follow-up: Monitor and Evaluate*

- Changes of lower extremity PAD symptoms (eg, claudication pain) and improvements in quality of life
- Presence of adverse drug reactions (eg, signs and symptoms of bleeding for those receiving an antiplatelet agent; Table e35-5)
- Walking assessment
- Adherence to pharmacotherapy and nonpharmacotherapy treatment plans using multiple sources of information
- Reevaluate therapy every 3 to 6 months

*Collaborate with patients, caregivers, and other healthcare professionals.

(ABI, ankle-brachial index; BP, blood pressure; DM, diabetes mellitus; PAD, peripheral arterial disease)

TREATMENT

Desired Outcomes

Overarching treatment principles for patients with lower extremity PAD include an improvement or alleviation of symptoms, reduction of ASCVD risk, and prevention of limb loss. Specific goals related to symptom improvement include increasing maximum walking distance, walking duration, pain-free walking, and overall quality of life. Specific goals to reducing ASCVD risk include lowering the risk of myocardial infarction (MI), stroke, and death, as well as control of modifiable risk factors (ie, achievement of goal blood pressure [BP], low-density lipoprotein cholesterol (LDL-C), hemoglobin A1C and smoking cessation, as appropriate).[3,37,38]

General Approach to Treatment

Several key risk factors play important roles in the morbidity and mortality of patients with PAD. Many of these risk factors are modifiable using various nonpharmacologic and pharmacologic interventions. Optimization of cardiometabolic risk factors and smoking cessation have demonstrated improvements in morbidity and/or mortality in patients with PAD.[3,9,39] However, there is insufficient evidence that therapies to lower homocysteine concentrations (ie, folic acid, vitamins B6 and B12, and/or betaine) improve lower extremity PAD symptoms or reduce the risk of complications.[17,40] Patients with PAD should be counseled on the importance of receiving an annual influenza vaccine to lower their risk of CV events.[3]

Risk Factor Modification

Tobacco Smoking Cessation

⑥ Tobacco smoking cessation is key for those with PAD who continue to smoke. Clinicians should assist patients with PAD who are currently smoking tobacco products by connecting them to a tobacco cessation program and/or provision of pharmacotherapy for tobacco smoking cessation. Pharmacotherapeutic options for tobacco smoking cessation include nicotine replacement therapy (NRT; eg, nicotine patches, lozenges, gum), bupropion, and varenicline. All lots of varenicline were recalled in September 2021. Clinicians are encouraged to check the Food and Drug Administration website for updates.[41] These tobacco cessation products are described in detail in Chapter 45 ("Chronic Obstructive Pulmonary Disease"). In all patients with PAD, whether current, former, or nonsmokers, avoidance of second-hand tobacco smoke is also important for reducing their risk of tobacco smoke-related complications.[3]

Cardiometabolic Disease Management

HTN, DM, and dyslipidemia assessment and treatment optimization are key to ASCVD risk reduction in patients with PAD. Current HTN guidelines recommend treating patients with PAD similar to those with ASCVD.[42] In patients with PAD, the BP goal should be < 130/80 mm Hg, and preference should be given to the use of either an angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB) as first-line therapy.[43] While not recommended as a first-line agent to treat hypertension, it is important to note that β-blockers are appropriate in patients with PAD who have a compelling indication for use (eg, heart failure with a reduced ejection fraction, history of MI). β-Blockers do not worsen IC in patients with PAD, a previous concern with this medication class.[44]

Analogous to current HTN guidelines, current lipid guidelines classify PAD as a form of ASCVD. As such, patients with PAD should be treated with high-intensity statin therapy with a goal of ≥50% LDL-C reduction. In patients with PAD who are at very high risk (eg, multiple ASCVD events or 1 ASCVD event with multiple high-risk conditions), adjunctive therapy should be considered if the LDL-C threshold of <70 mg/dL (1.81 mmol/L) is not met with statin therapy alone. Ezetimibe and/or a proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitor can be added to statin therapy to optimize LDL-C reduction and overall ASCVD risk.

Guideline recommendations for the treatment of T2DM in patients with PAD are similar to those for patients with other forms of ASCVD.[38] Use of a glucagon-like peptide-1 (GLP-1) receptor agonist and/or sodium-glucose cotransporter 2 (SGLT2) inhibitor is recommended by the American Diabetes Association for those with T2DM and either established ASCVD or indicators of high ASCVD risk (eg, lower extremity artery stenosis >50%) due to the established CVD benefits. Use of an agent with proven benefit from one or both classes is recommended regardless of metformin use, baseline A1C, and target A1C.[38]

Good glycemic control is key to risk mitigation in patients with PAD. The Atherosclerosis Risk in Communities (ARIC) study demonstrated that patients with poor glycemic control (A1C >7.5% [58 mmol/mol]) were five times more likely to develop IC and to be hospitalized for PAD compared with those with an A1C < 6% (42 mmol/mol).[45] Establishment of a patient-specific hemoglobin A1C target and selection of the most appropriate antihyperglycemic regimen are discussed in Chapter 94 ("Diabetes Mellitus").

Dosing, monitoring guidelines, and contraindications for specific agents used in the treatment of hypertension, DM, and dyslipidemia may be found in Chapters 30 ("Hypertension"), 94 ("Diabetes Mellitus"), and 32 ("Dyslipidemia").

Nonpharmacological

Nonpharmacological treatment options for PAD help improve various outcomes including reducing the risk of limb loss as well as improvement in the quality of life.[3,39,46,47] Both tobacco cessation (discussed above) and exercise programs are recommended for appropriate patients with PAD.

⑦ There are two types of exercise programs that have been found to be beneficial for those with symptomatic PAD. One is termed a *supervised* program and the other is *structured*. These program types are compared in Table e35-2. Appropriate screening of patients to determine the safety of one of these programs is key to avoiding adverse effects related to exercise.[3] In addition to helping with symptoms of claudication, appropriate exercise can improve other cardiometabolic risk factors by reducing weight, BP, blood glucose, and LDL-C.[48] Limited evidence suggests that participation in an exercise training program may improve walking distance in those with asymptomatic PAD.[49]

TABLE e35-2

Supervised Versus Structured Exercise Training

	Supervised	**Structured**
Location	Clinical setting (eg, hospital, outpatient facility)	Nonclinical setting preferred by the patient (eg, home)
Guidance	Direct supervision and instruction by a healthcare provider	Self-directed; healthcare provider counsels the patient on an exercise regimen "Coach" to hold patient accountable
Exercise	Walking on a treadmill until moderate-to-maximum claudication symptoms develop, alternating with rest Goal to reach the onset of symptoms within 3-5 minutes of walking; rest period typically lasts 2-5 minutes At least 3 sessions per week, each lasting at least 30-45 minutes	Written how to start and progress through the program by increasing the walking distance or speed Individualized plan; goal to achieve walking for 45-50 minutes, not including rest periods 3-5 times per week
Program duration	At least 12 weeks, ideally 6 months	At least 6 months

Data from References 3,49,50.

For those with DM, self-foot examination and healthy foot behaviors are imperative to minimize the risk of tissue loss or amputation. This includes wearing socks and shoes, selection of appropriate footwear, and daily inspection of the feet.[51] All patients with PAD should rapidly seek medical attention if there is any concern for foot infection (eg, local pain/tenderness, peri-wound edema, discharge, foul odor, visible bone). This will allow prompt assessment and treatment (if an infection is present) to minimize the risk of serious consequences.

⑧ Lower extremity revascularization is a therapeutic option for those with PAD symptoms when nonpharmacological, including structured exercise, and pharmacological treatment options fail to improve or maintain quality of life and functional status at a level suitable for the patient. Revascularization is necessary for those who develop CTLI or acute limb ischemia. Revascularization can be achieved through an endovascular procedure (eg, angioplasty, stenting) or surgery. Factors to determine which approach is best for an individual are beyond the scope of this Chapter. Readers wishing to learn more about this topic are referred to the 2016 American Heart Association/American College of Cardiology (AHA/ACC) Guideline on the Management of Patients with Lower Extremity Peripheral Artery Disease.[3]

Herbal remedies and dietary supplements have been promoted and/or investigated in those with PAD. These include vitamin B complex and flaxseed/flaxseed oil.[40,52] There is no evidence to suggest that the use of these or other supplements plays a role in the management of PAD.

Pharmacological

In addition to ASCVD risk reduction strategies previously discussed, pharmacological treatment options for PAD are determined based on several factors including the presence or absence of symptoms. Guideline recommendations for patients with PAD are summarized in Table e35-3 and recommendations for antithrombotic therapy following lower extremity revascularization are detailed in Table e35-4. Dosing recommendations, adverse drug reactions, and practical considerations for the antithrombotic agents and cilostazol which will be discussed in this section and can be found in Table e35-5.

TABLE e35-3

American Heart Association/American College of Cardiology Recommendations for Those with Peripheral Arterial Disease

Treatment Option	Recommendations for Use and Potential Benefit(s)	Class of Recommendation	Level of Evidence
Antithrombotic Therapy[a]			
Aspirin or clopidogrel (Plavix®) monotherapy	Symptomatic PAD: recommended to reduce the risk of vascular death, MI, and stroke Asymptomatic PAD (ABI ≤ 0.9): reasonable to reduce the risk of vascular death, MI, or stroke Asymptomatic PAD (ABI 0.91-0.99): usefulness to reduce the risk of vascular death, MI, or stroke is uncertain	I IIa IIb	A C-EO B-R
Oral anticoagulation[b]	All patients with PAD: oral anticoagulation should not be used to decrease the risk of ischemic events; use increases the risk of bleeding without any clinical benefit	III: Harm	A
Treatment of claudication			
Supervised exercise program	Claudication: recommended to decrease leg symptoms, and improve quality of life and functional status Discuss as a treatment option prior to possible revascularization	I I	A B-R
Structured exercise program (community- or home-based)	Symptomatic PAD: can be beneficial to improve functional status and walking ability	IIa	A
Cilostazol (Pletal®)	Claudication: effective option to improve walking distance	I	A
Risk factor modification			
Antihypertensive therapy	Hypertension and PAD: administer to lower the risk of CV death, MI, heart failure, and stroke	I	A
Glycemic control	Glycemic control can be beneficial for patients with CLTI to lower the risk of limb-related outcomes	IIa	B-NR
High-intensity HMG-CoA-reductase Inhibitor (statin)[c]	All patients with PAD: recommended to reduce the CV and risk of limb-related events (eg, worsening claudication, lower extremity revascularization); improve walking distance in those with intermittent claudication	I	A
Tobacco cessation	All patients with PAD: recommended to decrease the risk of death, ischemic CV events, limb-related events, and amputation	I	A

[a] Refer Table e35-4 for recommendations following lower extremity revascularization.

[b] Guideline preceded the publication of rivaroxaban data in this patient population.

[c] High-intensity statin regimens include atorvastatin 40-80 mg daily or rosuvastatin 20-40 mg daily.

ABI, ankle-brachial index; CLTI, chronic limb-threatening ischemia; CV, cardiovascular; MI, myocardial infarction; PAD, peripheral arterial disease.

Class of recommendation: I = strong, benefit >>> risk; IIa = moderate, benefit >> risk; IIb = weak, benefit ≥ risk; III: no benefit = moderate, benefit = risk; III: Harm = strong, risk > benefit.

Level of evidence: A = high-quality evidence from more than 1 randomized controlled trial (RCT); meta-analyses of high-quality RCTs; one or more RCTs corroborated by high-quality registry studies; B-R = moderate-quality evidence from one or more RCTs; meta-analyses of moderate-quality RCTs; B-NR = moderate-quality evidence from one more well-designed, well-executed nonrandomized studies, observational studies, or registry studies; C-LD = randomized or nonrandomized observational or registry studies with limitations of design or excretion; meta-analyses of such studies; physiological or mechanistic studies in human studies; C-EO = consensus of expert opinion based on clinical experience.

Data from Reference 3.

TABLE e35-4

Antithrombotic Recommendations Following Lower Extremity Revascularization for Peripheral Arterial Disease

Treatment Option	Recommendations for Use and Potential Benefit(s)	Class of Recommendation	Level of Evidence
Antiplatelet therapy			
Monotherapy: Aspirin 75-100 mg once daily or clopidogrel 75 mg once daily	Recommended to reduce the risk of vascular death, MI, and stroke	I	A
Dual antiplatelet therapy: Aspirin 75-100 mg once daily and clopidogrel 75 mg once daily	Lower extremity revascularization: use may be reasonable to lower the risk of limb-related events (eg, need for repeat revascularization)	IIb	C-LD
Oral anticoagulation			
Rivaroxaban 2.5 mg twice daily in combination with aspirin 81 mg/day[a]	Lower extremity revascularization: may be considered to reduce the risk of CV events or lower extremity ischemic events	NA	NA
Warfarin (adjusted to an INR goal of 2.0-3.0)	Following autogenous vein or prosthetic bypass: usefulness of uncertain	IIb	B-R

CV, cardiovascular; NA, not applicable.

Class of recommendation: I = strong, benefit >>> risk; IIa = moderate, benefit >> risk; IIb = weak, benefit ≥ risk; III: no benefit = moderate, benefit = risk; III: Harm = strong, risk > benefit.

Level of evidence: A = high-quality evidence from more than 1 randomized controlled trial (RCT); meta-analyses of high-quality RCTs; one or more RCTs corroborated by high-quality registry studies; B-R = moderate-quality evidence from one or more RCTs; meta-analyses of moderate-quality RCTs; B-NR = moderate-quality evidence from one more well-designed, well-executed nonrandomized studies, observational studies, or registry studies; C-LD = randomized or nonrandomized observational or registry studies with limitations of design or excretion; meta-analyses of such studies; physiological or mechanistic studies in human studies; C-EO = consensus of expert opinion based on clinical experience.

[a] Guideline preceded the publication of rivaroxaban data in this patient population.

TABLE e35-5

Overview of Select Pharmacotherapeutic Treatment Options for Those with Lower Extremity Peripheral Arterial Disease

Agent	Key Pharmacological Considerations	Dosing and Administration	Drug Interactions	Adverse Drug Reactions	Comments
Aspirin	Platelet binding:	75-100 mg orally	Nonsteroidal anti-inflammatory drugs, other	Bleeding,	Contraindicated

	irreversibly inhibits thromboxane A_2 formation Absorption (oral): immediate release – complete; enteric-coated – erratic Metabolism: rapid, hydrolysis to salicylic acid Duration of antiplatelet effect: 10 days (life of the platelet)	once daily Rectal formulation available	antiplatelets, anticoagulants: may increase bleeding risk	dyspepsia gastrointestinal ulcer, allergic reaction	in those with a hypersensitivity to nonsteroidal anti-inflammatory drug products
Clopidogrel	Platelet binding: irreversibly to the $P2Y_{12}$ receptor Metabolism: converted through a two-step process to the active metabolite; CYP2C19 is mostly involved Maximum inhibition of platelet aggregation: 5-7 days without a loading dose Duration of action: platelet aggregation returns to baseline within 5 days after discontinuation	75 mg orally once daily	CYP2C19 inhibitors[a]: may decrease efficacy of clopidogrel as it prevents formation of the active metabolite; avoid concomitant use of omeprazole and esomeprazole CYP 2C19 inducers (strong)[b]: may increase bleeding risk Non-steroidal anti-inflammatory drugs, other antiplatelets, anticoagulants: may increase bleeding risk	Bleeding, thrombotic thrombocytopenic purpura (rare)	Loading dose of therapy is not necessary Contraindicated in those with an active pathological bleeding (eg, peptic ulcer, intracranial hemorrhage) Role of CYP2C19 genetic testing for this patient population has not been substantiated
Cilostazol	Metabolism: CYP 2C19 and 3A4 (major) Elimination half-life: 11-13 hours Excretion: over 70% excreted in the urine; active metabolite concentrations increase in severe renal disease Onset of action: at least 2-4 weeks until walking distance impacted	100 mg orally twice daily Take 30 minutes prior or 2 hours after meals	CYP3A4 inhibitors (moderate and strong)[c]: can increase cilostazol exposure – decrease cilostazol dose to 50 mg twice daily when used in combination CYP2C19 inhibitors[a]: can increase cilostazol exposure – decrease cilostazol dose to 50 mg twice daily when used in combination Cigarette smoking: may decrease effectiveness of cilostazol	Abnormal stools, diarrhea, dizziness, headache, palpitations	Discontinue if no benefit observed after 12 weeks Contraindicated in those with heart failure as use may increase the risk of death
Rivaroxaban	Absorption: 2.5 mg dose is not affected by food Metabolism: hydrolysis and oxidative degradation	2.5 mg orally twice daily in combination with aspirin 75 -	CYP 3A4 (strong) and P-glycoprotein inducers[d]: avoid combination CYP 3A4 (strong) and P-glycoprotein inhibitors[e]: avoid combination	Bleeding	Take with or without food

	catalyzed by CYP 3A4, CYP3A5, CYP2J2 Elimination half-life: 5-9 hours Excretion: substrate of the P-glycoprotein efflux transporter proteins; about a third of unchanged drug is recovered in the urine	100 mg once daily Creatinine clearance < 30 mL/min (0.5 mL/s): limited data for use	CYP3A4 (moderate) and P-glycoprotein inhibitors[f]: may increase bleeding risk, do not use combination if creatinine clearance 15 to < 80 mL/min (0.25 to 1.33 mL/s) in combination unless benefit outweighs bleeding risk Nonsteroidal anti-inflammatory drugs, antiplatelets, other anticoagulants: may increase bleeding risk		

CYP: cytochrome P.

[a] Fluconazole, omeprazole, ticlopidine.

[b] Rifampin.

[c] **Moderate**: erythromycin, diltiazem, grapefruit juice, etc.; **strong**: ketoconazole.

[d] Carbamazepine, phenytoin, rifampin, St. John’s wort, etc.

[e] Ketoconazole, ritonavir, etc.

[f] Erythromycin.

Antithrombotic Agents

Antiplatelets

Platelets play a significant role in the pathogenesis of atherothrombosis. In patients with atherosclerotic disease, including those with PAD, plaque formation occurs within the arterial lumen. In patients with PAD, plaque rupture can occur, which can result in atherothrombosis leading to tissue loss in the lower extremities, MI, stroke, and/or death. Platelets begin to adhere to the vessel wall after an injury occurs (ie, plaque rupture). Platelets then become activated and platelet agonists, including adenosine diphosphate (ADP) and thromboxane A_2, are released and promote platelet aggregation. ADP induces platelet aggregation by binding to the $P2Y_{12}$ receptor on the platelet. These aggregated platelets make up part of the thrombosis that develops in response to vessel injury.[dipipharm12_c035_bib058,dipipharm12_c035_bib059] A more detailed discussion of arterial thrombus formation in response to ruptured atherosclerotic plaques is provided in Chapter 34 (“Acute Coronary Syndrome”).

Several antiplatelet therapies have been developed in an attempt to mitigate atherothrombosis formation. Aspirin and clopidogrel are the antiplatelet therapies recommended for use in select patients with PAD. Aspirin is an irreversible thromboxane A_2 inhibitor. Clopidogrel, following metabolism to its active form, prevents ADP from binding to the $P2Y_{12}$ receptor.[60,61]

⑨ Aspirin has been a mainstay for secondary prevention of CVD for decades due to its antiplatelet properties. A meta-analysis assessing the impact of antiplatelet therapy of ischemic events in those with known vascular disease or at high risk for atherosclerotic disease, including those with PAD (history of IC, peripheral grafting, or angioplasty), demonstrated that antiplatelet therapy was associated with a 23% reduction in vascular events in the PAD subgroup.[60] This analysis also demonstrated that a lower daily dose of aspirin (75-150 mg) is as effective as higher doses (≥ 160 mg daily) in reducing CV events in those with known vascular disease.[60] These observations established the role of aspirin for those with symptomatic PAD. More recent trials sought to identify if there was a benefit of antiplatelet therapy in those without PAD symptoms.

The Prevention of Progression of Arterial Disease and Diabetes (POPADAD) trial compared the use of aspirin (100 mg/day) to placebo in patients with DM and asymptomatic PAD. No differences were observed between groups in the risk of death from coronary heart disease or stroke, nonfatal MI or stroke, or above the ankle amputation for CLTI.[62] The Aspirin for Asymptomatic Atherosclerosis trial randomized patients with an ABI ≤ 0.95 to aspirin (100 mg/day) or placebo and observed no difference in the risk of fatal or nonfatal coronary events or stroke between groups.[62] Aspirin use was associated with an increased risk of the first major hemorrhagic event. These two trials called into question the routine use of aspirin in those with asymptomatic PAD.

Clopidogrel was compared to aspirin in patients with stable atherosclerotic disease in the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) study. Approximately, one-third of the study population had symptomatic lower extremity PAD, defined as IC with an ABI ≤ 0.85 or less, prior revascularization or amputation. Although the use of clopidogrel was associated with a lower overall risk of the primary composite outcome (MI, stroke, or vascular death) compared to aspirin, subgroup analyses found event rates were significantly lower in the PAD subgroup but not the MI and stroke subgroups.[61] The aspirin dose in this trial was higher (325 mg once daily) than currently recommended.[3] Severe bleeding events were low and comparable between groups. Therefore, it is unlikely that a lower dose of aspirin would have been associated with a lower risk of bleeding compared to clopidogrel. Although this trial was not powered to determine the superiority of clopidogrel over aspirin in patients with symptomatic PAD, it provides evidence that clopidogrel is a suitable alternative to aspirin in this population. The use of clopidogrel has not been evaluated in those with asymptomatic PAD.

The combination of aspirin and clopidogrel (dual antiplatelet therapy or DAPT) in patients with PAD was evaluated in the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial to determine if this more potent antiplatelet regimen would result in a lower risk of CV events (MI, stroke, or CV) in those with established ASCVD, including those with symptomatic PAD. The DAPT regimen was associated with an increased risk of bleeding and no difference in CV events when compared to aspirin monotherapy.[63] Therefore, the use of DAPT should not be recommended for an individual with PAD unless another indication for use exists (eg, revascularization, MI).[3]

Ticagrelor, a more potent $P2Y_{12}$ receptor antagonist compared to clopidogrel, was evaluated in patients with symptomatic lower extremity PAD. In the Examining Use of Ticagrelor in Peripheral Artery Disease (EUCLID) trial, the use of ticagrelor was not associated with a lower risk of CV events when compared to clopidogrel. Bleeding rates were comparable between the two groups.[64] Now, there is no role for ticagrelor or prasugrel, another potent $P2Y_{12}$ receptor antagonist, for patients with PAD.

In the absence of another indication for use, aspirin is typically selected as the antiplatelet therapy for most patients with established ASCVD, including those with symptomatic PAD, given its low cost and availability over-the-counter (OTC). The dose of aspirin should be 75 to 100 mg once daily. Higher doses have not been shown to improve clinical outcomes but are associated with a higher risk of bleeding.[60,65] The enteric-coated formulation of aspirin was developed to minimize the risk of gastrointestinal toxicity associated with the use of this agent. Absorption of the enteric-coated product is variable and influenced by several variables (eg, food, alcohol). Variable absorption could affect the effectiveness of therapy. There is no evidence that enteric-coated formulations of aspirin decrease the risk of gastrointestinal adverse drug reactions.[66–68] Therefore, the noncoated formulation is recommended.

It is reasonable to consider clopidogrel as the first-line antiplatelet agent. Care should be taken to assess for the presence of drug interactions that could alter the metabolism of clopidogrel before initiating therapy. For example, select cytochrome P450 (CYP) 2C19 inhibitors (eg, omeprazole) will decrease the conversion of clopidogrel to its active metabolite, potentially leading to decreased efficacy. Clopidogrel, available by prescription only, should be utilized in those with a hypersensitivity to aspirin. Unlike patients treated with clopidogrel for acute coronary syndrome, loading doses of antiplatelet therapies are not necessary for those with PAD because there is not an urgent need to achieve maximum platelet inhibition.[69,70]

Patients should be counseled to monitor for and informed to report signs or symptoms of bleeding. Clinicians should assess for signs and symptoms of bleeding during each patient visit. Periodic assessment of hemoglobin/hematocrit should be considered in those at a higher risk of bleeding (eg, older patients). When a significant decrease in hemoglobin or hematocrit is identified, the cause for blood loss, including the use of antiplatelet therapies, should be investigated. Patients should be counseled against the use of a nonsteroidal anti-inflammatory agent in combination with aspirin or clopidogrel as there is an additive risk of bleeding.

Oral Anticoagulant Therapy

Despite the use of antiplatelet therapy, CV events and limb loss can occur in those with PAD. In addition to stimulating platelet aggregation, plaque rupture also leads to activation of the coagulation cascade with thrombin and other coagulation proteins being generated. Thrombin plays a critical role in stabilizing the clot that forms following activation of the coagulation system. Thrombin also converts fibrinogen to fibrin, which solidifies the clot. While arterial thrombi are rich in platelets, fibrin becomes the primary component as thrombi extend distally.[71]

Anticoagulants have been studied in the PAD population as an additional treatment option to lower the risk of CV events as well as limb-threatening events. These agents increase clotting time within the blood. Two oral anticoagulants, warfarin and rivaroxaban, have been evaluated in this patient population. Warfarin has a complex mechanism of action but ultimately results in reduced production of clotting factors II, VII, IX, and X. Rivaroxaban, a direct-acting oral anticoagulant, inhibits Factor Xa. Factor Xa is responsible for the formation of active thrombin (Refer to Chapter 38 : Venous Thromboembolism for more details on the mechanism of action and the pharmacokinetic and pharmacodynamic properties of these agents).

In patients with PAD, warfarin, adjusted to a target international normalized ratio of 2.0 to 3.0, in combination with an antiplatelet was associated with more than a threefold increased risk of life-threatening bleeding without an incremental benefit in lowering CV risk when compared to antiplatelet therapy alone.[72] Consequently, warfarin is not recommended in those with PAD without another indication for use.[3]

Rivaroxaban has been studied as a secondary prevention strategy in combination with aspirin in patients with stable atherosclerotic disease. The Cardiovascular Outcomes for People Using Anticoagulation Strategies (COMPASS) trial compared rivaroxaban 2.5 mg twice daily in combination with aspirin 100 mg daily; rivaroxaban monotherapy (5 mg twice daily); or aspirin monotherapy (100 mg daily) in patients with stable atherosclerotic disease, including 15% with lower extremity PAD.[73] Overall, combination therapy with low-dose rivaroxaban and aspirin was associated with a 24% lower risk of CV death, MI, or stroke compared to aspirin monotherapy; no differences were observed between the rivaroxaban monotherapy and aspirin groups. The benefit was driven by a reduction in the risk of CV death and stroke. A sub-group analysis of the PAD cohort revealed the combination of rivaroxaban 2.5 mg twice and aspirin was associated with a 43% lower risk of major adverse limb events including amputation and vascular intervention compared to aspirin monotherapy. Major bleeding was 60% higher in the combination group compared to those only receiving aspirin.[74]

⑩ The Vascular Outcomes Study of ASA (acetylsalicylic acid) Along with Rivaroxaban in Endovascular or Surgical Limb Revascularization for PAD (VOYAGER PAD) study demonstrated that the use of rivaroxaban 2.5 mg twice daily, in combination with aspirin (100 mg/day), was associated with a 15% reduction in the risk of acute limb ischemia, major amputation for vascular causes, MI, ischemic stroke, or CV death compared to aspirin monotherapy in patients with PAD who underwent recent revascularization. This difference was driven by a reduction in acute limb ischemia between groups.[53] Like COMPASS, major bleeding was more common in the rivaroxaban group.

⑩ The use of aspirin, clopidogrel, or the combination of these two agents is recommended post-revascularization in the AHA/ACC Lower Extremity PAD guideline (Table e35-4.).[2] This guideline has not been updated since the COMPASS and VOYAGER PAD trials were published. While these data are compelling, it is prudent to have more robust evidence exploring the use of this regimen in those with symptomatic lower extremity PAD population that did not undergo revascularization before rivaroxaban can be routinely recommended for this group. There is a role for rivaroxaban 2.5 mg twice daily in combination with low-dose aspirin in those who underwent lower extremity revascularization. Shared decision-making should be employed before prescribing this regimen. The potential benefit and risk of bleeding should be weighed for each person. Clinicians should ensure that the correct dose is used for PAD as various dosing regimens and dosage forms exist for rivaroxaban.[54] Rivaroxaban is renally eliminated; therefore, the potential for increased risk of bleeding exists in patients with CKD stage 4 or 5. Because there is limited data to support the use of low-dose rivaroxaban in those with a creatinine clearance <30 mL/min (0.5 mL/s), it may be prudent to avoid rivaroxaban in this setting until more data is available.

Cilostazol

Cilostazol, a phosphodiesterase-3 inhibitor, improves peripheral vasodilation potentially leading to improved blood flow in the lower extremities.[55] However, the exact mechanism of this agent in those with PAD remains unclear. Cilostazol is considered an add-on therapy for individuals who have persistent PAD symptoms despite smoking cessation, if applicable, and participation in an exercise program.[3,75] Compared to placebo, cilostazol use was associated with a mean increase of 43 m in distance walked on the treadmill before the development of claudication symptoms.[76] A meaningful change is considered 20 to 50 m when using the 6-minute walking test.[49] Therefore, while the magnitude of the effect may be less than that of a supervised exercise program, the improved walking distance associated with cilostazol may allow a patient with PAD to walk across a room without provoking symptoms, for example.

The presence of drug interactions (Table e35-5) should be assessed prior to initiating and during cilostazol therapy, and dose adjustments made as necessary. Clinicians should assess for the presence of heart failure before implementing therapy. Cilostazol has been associated with an increased risk of death in patients with heart failure and is, therefore, contraindicated in this population.[55]

Improvements in symptoms may begin as early as 4 weeks after initiation of cilostazol but it may take up to 12 weeks for any benefit to occur. This expectation should be clearly communicated to the patient. If symptomatic improvement is observed, there may be a progressive benefit over the first 12 to 24 weeks of therapy. Thereafter, the benefit of therapy will plateau.[77,78] Treatment should be stopped in those who have not experienced symptomatic improvement after 12 weeks since there is no evidence that any benefit will develop after this time if it has not already occurred.[3,55] There is no evidence that increasing the dose above 100 mg twice daily is associated with a greater benefit.

Other Therapies

Protease-activated receptor (PAR)-1 is a receptor for thrombin on the surface of platelets that plays a role in platelet activation. Vorapaxar is a PAR-1 antagonist that has been evaluated in combination with aspirin in patients with stable CVD, including those with PAD.[79] Vorapaxar in combination with aspirin was shown to decrease the risk of revascularization in participants with lower extremity PAD. However, this benefit was outweighed by an increased risk of bleeding. Importantly, vorapaxar increases the risk of intracranial hemorrhage and is contraindicated in those with prior stroke or transient ischemic attack. The AHA/ACC Lower Extremity PAD guideline notes that the overall benefit for this agent is uncertain.[3] Pentoxifylline is not an effective agent for managing claudication symptoms and is not recommended by AHA/ACC.[3] Now, neither vorapaxar nor pentoxifylline should not be considered for any individuals with PAD.

EVALUATION OF THERAPEUTIC OUTCOMES

There are several methods that should be employed for monitoring those with PAD. First, it is imperative to assess and control ASCVD risk factors to lower the patient's overall risk of death and CV events.[3] BP measurements should be taken at each office visit and HTN treatment should be initiated or optimized as necessary. Home BP or ambulatory BP monitoring may be necessary for some patients to determine if their goal is being met.[42] A baseline A1C should be determined at the time of PAD diagnosis to evaluate the presence and control of DM. A repeat A1C should be completed at least every 3 years for a person 45 years of age or older who has not been previously diagnosed with T2DM. Repeat A1C testing can occur sooner based on the clinician's judgment.[80] Refer to Chapters 30, Hypertension , 32, Dyslipidemia, and 94, Diabetes Milletus,for more specific information on the frequency of monitoring and strategies to achieve BP, cholesterol, and glycemic goals, respectively. Tobacco use should be addressed at each patient encounter, even in those who never smoked. Assessment for the risk of relapse should be conducted in former smokers.[81]

Inquiries about new CV events (ie, MI, stroke, sudden cardiac death) should be completed at each visit. A review of symptoms to assess for signs and symptoms of CVD and cerebrovascular disease should be completed at each visit. When present, clinicians should recommend additional strategies to lower one's ASCVD risk, if possible.

Clinicians should assess for changes in functional status and lower extremity symptoms during each patient encounter.[3] The details reported by the patient should be documented (eg, distance walked when pain begins). This can assist providers in determining if symptoms and/or functional limitations change over time. Physical examination findings should be clearly documented for similar reasons. Reports from the exercise training program, when part of the treatment plan, should also be reviewed to allow for a comprehensive assessment of functional status and symptoms.[3]

Recommendations for repeat testing and imaging are presented in the box. There is not a consensus on when follow-up ABI testing should occur in a patient who has not undergone lower extremity revascularization. Clinical decision-making should likely drive this decision, including when there is a significant decline in functional status. It is important that ABI testing be done in both limbs during follow-up even if there was not a prior diagnosis of PAD in both lower extremities. A decrease in an ABI score of >0.15 is considered to be evidence of significant lower extremity PAD progression.[82] Therefore, when this magnitude of change in ABI is detected, more routine follow-up should occur. Imaging is necessary when revascularization will be considered for those with symptomatic PAD despite guideline-directed medical therapy.[3,14] Consultation with a vascular specialist should occur to determine which test(s) is most appropriate.

A biannual foot examination can be conducted in those who have DM and may assist in reducing the risk of tissue loss as a clinician may be more like to identify a foot infection than a patient. In patients with PAD and DM, peripheral neuropathy can make the signs of this infection more subtle. Thus, further evaluation may not be sought out as quickly if depending solely on patient reports.[3]

Recommendations for Longitudinal Testing and Imaging in Those with PAD[3,14]

- Duplex ultrasound, computerized tomography angiography, or magnetic resonance angiography is useful to determine the anatomic location and severity of stenosis when revascularization is being considered for a patient with symptoms
- Invasive angiography is useful for patients who may undergo revascularization with CLTI and is reasonable when revascularization is being considered for those with life-limiting claudication who do not respond to guideline-directed medical therapy
- Periodic ABI testing should occur for those who have undergone lower extremity revascularization but should not be used alone to monitor these patients
- Surveillance duplex ultrasound can be beneficial for those who have undergone infrainguinal, autogenous bypass grafts
- Surveillance duplex ultrasound is reasonable after endovascular procedures

During each patient encounter, patients should be evaluated for the presence of adverse drug reactions and scenarios that may increase the risk of adverse events. For patients treated with antithrombotic therapy, clinicians should assess for the presence of signs and symptoms of bleeding. Renal function should be evaluated periodically for patients treated with rivaroxaban. Clinicians should screen patients treated with cilostazol for the development of concomitant heart failure. Lastly, clinicians should evaluate for the presence of drug-drug interactions during each patient encounter.

CONCLUSION

PAD is underrecognized despite the known serious consequences of this condition. Assessing for the presence of symptoms and physical examination findings suggestive of PAD should occur in those at risk. Identification of signs and symptoms of PAD should prompt subsequent diagnostic testing. The ABI is the most common diagnostic tool used as it is noninvasive and relatively easy to complete.

Treatment of PAD consists of ASCVD risk reduction strategies including achievement of BP, glycemic, and cholesterol goals. Patients with PAD should receive high-intensity statin therapy unless contraindicated. Antithrombotic therapy with either low-dose aspirin or clopidogrel is recommended in those with symptoms of PAD to lower the risk of death, MI, and stroke.

Both nonpharmacological and pharmacological options exist to manage PAD symptoms. Tobacco smoking cessation is one of the most effective methods to improve symptoms and to prevent complications of PAD including the risk of amputation. Exercise training is an effective nonpharmacological treatment option to decrease symptoms and improve functional capacity. Cilostazol may be considered as a treatment option for those who continue to have PAD symptoms despite smoking cessation and participation in an exercise program.

Lower extremity revascularization is an option for some patients when symptoms are not controlled despite optimization of other treatments. An antithrombotic regimen should be prescribed following revascularization. Treatment options include low-dose aspirin or clopidogrel monotherapy; low-dose aspirin and clopidogrel used in combination; or rivaroxaban 2.5 mg twice daily and low-dose aspirin.

SELF-ASSESSMENT QUESTIONS

1. Which of the following risk factors is most strongly associated with the development of peripheral arterial disease (PAD)?

   A. Current tobacco smoking

   B. Diabetes

   C. Dyslipidemia

   D. Hypertension

2. A 53-year-old male with a medical history notable for hypertension (HTN), dyslipidemia, myocardial infarction (MI) 3 years ago, and a previous 30 pack-year smoking history presents to your clinic for follow-up. Physical exam is notable for bilateral lower leg and foot pain and cramping during daily walks. Vital signs include height 5′11″ (180 cm), weight 91 kg, blood pressure (BP) 138/90 mm Hg, HR 80 bpm, T 37°C. Laboratory values include hemoglobin A1C 6.1% (43 mmol/mol), low-density lipoprotein cholesterol (LDL-C) 100 mg/dL (2.59 mmol/L), high-density lipoprotein cholesterol (HDL-C) 40 mg/dL (1.03 mmol/L), triglycerides (TG) 150 mg/dL (1.70 mmol/L), total cholesterol (TC) 170 mg/dL (4.40 mmol/L). Which of the following patient findings is most indicative of PAD?

   A. Hemoglobin A1C 6.1% (43 mmol/mol)

   B. History of tobacco smoking

   C. LDL-C 100 mg/dL (2.59 mmol/L)

   D. Lower extremity pain and cramping during exertion

3. Which of the following ankle-brachial index (ABI) measurements is consistent with a diagnosis of lower extremity PAD?

   A. 1.4

   B. 1-1.4

   C. 0.91-0.99

   D. ≤0.9

4. Which of the following is a symptom improvement goal when treating lower extremity PAD?

   A. Improved BP control

   B. Pain-free walking

   C. Reduced risk of MI

   D. Smoking cessation

5. Which of the following is TRUE regarding hypertensive management in a patient with lower extremity PAD?

   A. β-Blockers should be used first-line

   B. Calcium channel blockers should be used first-line

   C. BP goal is <130/80 mm Hg

   D. BP goal is <140/90 mm Hg

6. Which of the following statin choices would be best for optimizing cardiovascular risk reduction in a patient with lower extremity PAD?

   A. Atorvastatin 20 mg orally daily

   B. Lovastatin 20 mg orally daily

   C. Rosuvastatin 20 mg orally daily

   D. Simvastatin 20 mg orally daily

7. A 72-year-old patient develops intermittent claudication symptoms after walking 20 feet (6.1 m). Medical history includes coronary artery disease, heart failure with a reduced ejection fraction, and HTN. The patient does not smoke. BP is at goal. Medications, all taken once daily, include aspirin 81 mg, atorvastatin 80 mg, lisinopril 40 mg, and amlodipine 10 mg. Which of the following treatment options could be considered for this patient to improve his claudication symptoms?

   A. Cilostazol

   B. Clopidogrel

   C. Rivaroxaban

   D. Structured exercise program

8. The recommended dose for aspirin in those with symptomatic lower extremity PAD is

   A. 75 to 100 mg once daily.

   B. 75 to 100 mg twice daily.

   C. 100 to 325 mg once daily.

   D. 100 to 325 mg twice daily.

9. Which of the following is the correct antithrombotic regimen for a patient who will be initiated on rivaroxaban following lower extremity revascularization for PAD?

   A. 20 mg once daily with dinner

  B. 15 mg twice daily for 21 days then rivaroxaban 20 mg once daily
  C. 5 mg twice daily and aspirin 325 mg once daily
  D. 2.5 mg twice daily and aspirin 81 mg once daily

10. After how many weeks of therapy should cilostazol should be discontinued if no benefit is observed with use?
    A. 6 weeks
    B. 12 weeks
    C. 24 weeks
    D. 48 weeks
11. In a patient with lower extremity PAD, which of the following comorbidities or circumstances would vorapaxar use be contraindicated?
    A. Heart failure
    B. Type 1 diabetes mellitus
    C. Prior lower extremity revascularization
    D. Prior stroke or transient ischemic attack
12. What is the American Heart Association/American College of Cardiology recommendation for the use of pentoxifylline for those with lower extremity PAD?
    A. Use is not recommended
    B. Consider if antiplatelet therapy is contraindicated
    C. Initiate treatment when an exercise training program begins
    D. Reasonable to use if claudication symptoms persist despite smoking cessation
13. What is the American Heart Association/American College of Cardiology recommendation for the use of warfarin for those with lower extremity PAD who have not undergone revascularization?
    A. Use is not recommended
    B. Consider if antiplatelet therapy is contraindicated
    C. Initiate treatment when an exercise training program begins
    D. Reasonable to use if claudication symptoms persist despite smoking cessation
14. A 75-year-old patient with heart failure with reduced ejection fraction is diagnosed with PAD after undergoing ABI testing (ABI = 0.72). This test was recommended based on physical examination findings. The patient denies pain or discomfort in the lower extremities with exertion or at rest. The patient has no functional limitations due to PAD. The patient is currently not receiving any antithrombotic therapy. Which of the following recommendations is best regarding the use of clopidogrel in this patient?
    A. Recommended to prevent the development of PAD symptoms in the future
    B. Reasonable to lower the risk of cardiovascular events and death
    C. Not recommended because of the presence of heart failure

D. Not recommended as risk of bleeding outweighs any potential benefit

15. Which of the following nonpharmacological strategies has been shown to decrease the risk of amputation in patients with lower extremity PAD?

A. 10% reduction in body weight

B. Supervised exercise training

C. Structured exercise training

D. Tobacco cessation

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Current tobacco smoking is the risk factor most strongly associated with PAD. Diabetes (30%-80% increased risk), dyslipidemia (up to 14% increased risk), and hypertension (50% increased odds) each contribute to PAD risk, but to a lesser degree than current tobacco smoking. Refer to Introduction and Epidemiology sections for more information.

2. **D.** Lower extremity pain and cramping during exertion are most indicative of PAD. There is no specific lab test or laboratory value associated with PAD. His history of smoking is a risk factor for PAD, but is not diagnostic for the condition. The patient should undergo further assessment to determine if he has PAD as he has symptoms and risk factors for the condition. See the Clinical Presentation section for more information.

3. **D.** ≤0.9 is diagnostic of PAD (and can be further broken down into mild [0.7-0.9], moderate [0.4-0.7], and severe [<0.4]). The other answer choices indicate noncompressible arteries (>1.4), normal (1-1.4), and borderline risk for PAD (0.91-0.99). Refer to the Clinical Presentation (Diagnostic Tests) section for more information.

4. **B.** Pain-free walking is a treatment goal to improve symptoms for a person with PAD. The other answer choices are goals of treatment for PAD but are related to atherosclerotic cardiovascular disease (ASCVD) risk reduction rather than symptom improvement. Refer to the Treatment section for more information.

5. **C.** The blood pressure goal for those with PAD is <130/80 mm Hg; <140/90 mm Hg is not strict enough given that PAD indicates the presence of ASCVD. An angiotensin-converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB) should be used as a first-line agent. β-Blockers are only preferred if compelling indications exist (eg, post-myocardial infarction). Refer to the General Approach to Treatment (Risk Factor Modification, Cardiometabolic Disease Management) section for more information.

6. **C.** Patients with PAD should be treated with at least a high-intensity statin that will reduce their LDL-C levels by ≥50%. Rosuvastatin 20 mg orally daily is the only option that will result in this level of LDL-C reduction; all other options indicate moderate- (or low-) intensity statin therapy. Other high-intensity statin regimens are atorvastatin 40 to 80 mg once daily or rosuvastatin 40 mg once daily. Refer to the General Approach to Treatment (Risk Factor Modification, Cardiometabolic Disease Management) section for more information.

7. **D.** Structured exercise training has been shown to improve symptoms in those with lower extremity PAD. Refer to the Nonpharmacological section and Table e35-3 for more information. Cilostazol may provide improvement in symptoms but cannot be considered for this patient as he has heart failure (see Table e35-5). There is no evidence that the addition of clopidogrel or rivaroxaban improves symptoms in those with PAD. Refer to the Antithrombotic Agents section for more information.

8. **A.** The recommended dose of aspirin to reduce the risk of cardiovascular events and death in those with symptomatic PAD is 75 to 100 mg once daily. Higher doses (and increased dosing frequency) increase the risk of bleeding without improving efficacy. Refer to Table e35-5 and the Antithrombotic Section (Aspirin) for more information.

9. **D.** The regimen of rivaroxaban 2.5 mg twice daily and aspirin 81 mg once daily was found to be effective in lowering the risk of cardiovascular and limb-related events in the Cardiovascular Outcomes for People Using Anticoagulation Strategies (COMPASS) trial. There is no evidence that other rivaroxaban regimens produce similar results. See the Pharmacological (Antithrombotic Agents, Anticoagulation) section for more information.

10. **B.** Cilostazol should be discontinued if no benefit is observed after 12 weeks of use. See Table e35-5 for more information.

11. **D.** Use of vorapaxar is contraindicated in those with a prior history of stroke or transient ischemic attack. Use in this patient population is associated with an increased risk of intracranial hemorrhage. Refer to the Pharmacological (Other Therapies) section for more information.

12. **A.** Pentoxifylline has not been proven effective in those with PAD. Therefore, this agent is not recommended for any patients with PAD by the American Heart Association/American College of Cardiology. Refer to the Pharmacological (Other Therapies) section for more information.

13. **A.** Use of warfarin in combination with antiplatelet therapy in those with PAD is associated with an increased risk of life-threatening bleeding. There was no benefit of this combination therapy observed. Therefore, warfarin is not recommended for patients with PAD, without another indication for use, by the American Heart Association/American College of Cardiology owing to the risk of harm. Refer to the Pharmacological (Antithrombotic Agents, Anticoagulation) section and Table e35-3 for more information.

14. **B.** There is no clear evidence that the use of antiplatelet therapy (ie, aspirin or clopidogrel monotherapy) reduces the risk of cardiovascular events in those without PAD symptoms and an ABI ≤ 0.9. Therefore, the American Heart Association/American College of Cardiology notes that use is “reasonable” in this situation. The risk versus benefit would need to be discussed with the patient before starting antiplatelet therapy. Antiplatelet therapy does not prevent the development or progression of PAD symptoms (A). Cilostazol, not clopidogrel, has been associated with an increased risk of death in patients with heart failure (C). Refer to the Pharmacological (Antithrombotic Agents) section and Table e35-3 for more information.

15. **D.** Of these four potential options, tobacco cessation is the only nonpharmacological treatment strategy that has been shown to reduce the risk of amputation. See the Nonpharmacological section and Table e35-3 for more information.

Chapter e42: Shock Syndromes

Seth R. Bauer; Robert MacLaren; Brian L. Erstad

KEY CONCEPTS

KEY CONCEPTS

①The presence of shock is indicated by inadequate global tissue perfusion. Low blood pressures are not required to define shock.

②Shock is typically classified into one of the four etiologic mechanisms: (1) hypovolemic, (2) cardiogenic, (3) obstructive, or (4) vasodilatory/distributive.

③Shock syndromes can be differentiated based on the evaluation of preload, cardiac output, and afterload or assessment of surrogate markers.

④Inadequate oxygen delivery leads to organ damage in critical illness.

⑤Blood lactate should be measured in all patients in whom shock is suspected.

⑥Treatment of the patient with circulatory shock can be divided into four phases: salvage, optimization, stabilization, and de-escalation. Each phase has different but sometimes overlapping goals and therapeutic strategies.

⑦Crystalloid solutions are the first-line fluid of choice for forms of circulatory insufficiency that are associated with hemodynamic instability.

⑧Vasopressors and inotropes are required in patients with shock when volume resuscitation fails to maintain adequate blood pressure and tissues remain hypoperfused.

⑨The choice of a particular vasopressor or inotrope agent depends on the underlying shock pathophysiology, goals of therapy, and clinical pharmacology.

⑩Norepinephrine is the preferred initial vasopressor for shock.

BEYOND THE BOOK

BEYOND THE BOOK

Develop a table that has two columns, one titled crystalloid solutions and one titled colloid solutions. In each column, list at least four potential advantages and four potential disadvantages of the solution. There are several crystalloid and colloid solutions commercially available, so you will need to be specific about the solutions included in the table. The purpose of this exercise is to help students choose a preferred resuscitation fluid for a critically ill patient based on patient-specific data.

INTRODUCTION

Circulatory shock is a medical emergency requiring prompt recognition and treatment because it can quickly lead to serious consequences, including death. Shock is a broad term for a heterogeneous group of syndromes that cause an acute, generalized circulatory failure associated with inadequate oxygen utilization by the cells.[1] Typically, shock is characterized as systolic blood pressure (SBP) <90 mm Hg (or acute reduction of at least 40 mm Hg from baseline) or mean arterial blood pressure (MAP) <70 mm Hg with tachycardia and organ perfusion abnormalities.[2] The key feature of all shock syndromes is inadequate tissue and organ perfusion.

Learners are strongly encouraged to read Chapter e29 "Evaluation of Cardiovascular Function" and Chapter 142 "Sepsis and Septic Shock" to augment their understanding of the content in this chapter.

EPIDEMIOLOGY

Hemodynamic compromise necessitating the use of vasopressors is common in the intensive care unit (ICU), with about one-third of critically ill patients receiving vasopressors during their clinical course.[3] Shock is not a reportable cause of death to state and federal agencies and, thus, the true incidence is unknown. Reported mortality of patients with shock in clinical studies from the 1980s exceeded 70% but now ranges from 20% to 55%.[4–7] However, estimates of deaths due to shock are complicated by differences in definitions and classification systems. Normal compensatory mechanisms may reverse the processes leading to irreversible organ dysfunction. However, progressive circulatory insufficiency may result in the loss of these compensatory responses. Identification of when this occurs can be problematic as this varies from patient to patient and is not always readily apparent during the initial patient presentation. Therefore, forms of shock, such as hemorrhagic shock, are often subsumed by more readily identifiable categories of death, such as accidental injuries and homicides.

ETIOLOGY

① The presence of circulatory shock is indicated by inadequate global tissue perfusion. Circulatory shock develops when the cardiovascular system is unable to deliver an adequate oxygen supply to meet tissue oxygen demands, resulting in cellular dysfunction. This cellular dysoxia leads to a shift in cellular metabolism to anaerobic pathways and results in elevated blood lactate concentrations. Physiologically, tissue metabolic requirements are met by both adequate MAP and adequate oxygen delivery (DO_2). The MAP is the driving pressure for peripheral blood flow and end-organ perfusion. Tissue blood flow cannot be directly measured; therefore, MAP is used as a surrogate estimate. Because the components of blood pressure are cardiac output (CO) and systemic vascular resistance (SVR) and because CO is a determinant of DO_2, blood pressure is integrally related to DO_2. However, compensatory mechanisms such as vasoconstriction may preserve blood pressure while tissue perfusion is inadequate. Therefore, while low blood pressure is commonly present in patients with shock, it is not required to define shock.[1]

② Shock is typically classified into one of the four etiologic mechanisms: (1) hypovolemic, (2) cardiogenic, (3) obstructive, or (4) vasodilatory/distributive. Vasodilatory/distributive is the most commonly encountered shock syndrome, which accounts for about two-thirds of all shock cases requiring vasopressors. Cardiogenic and hypovolemic shock are both encountered in about 16% of cases, while obstructive shock is rarely encountered (about 2% of cases).[2] Notably, patients may have components of more than one shock syndrome on presentation (the categories are not mutually exclusive) and patients can transition from one shock type to another (eg, a patient with cardiogenic shock may subsequently develop septic shock, or a patient with septic shock may develop cardiogenic shock from a myocardial infarction). Hypovolemic, cardiogenic, and obstructive shock are all characterized by low CO, but the mechanism for low CO is different in each shock state. Hypovolemic shock is caused by inadequate venous return, from internal or external loss of intravascular fluids (eg, trauma, surgery, or hemorrhage), resulting in insufficient cardiac preload and decreased stroke volume. Cardiogenic shock results from a loss in pump function, through decreased cardiac contractility (eg, myocardial infarction), acute valvular abnormality, or an arrhythmia (eg, ventricular tachycardia). Obstructive shock results from an extracardiac obstruction to blood flow into or out of the heart, such as tension pneumothorax, cardiac tamponade, or pulmonary embolism.

Vasodilatory/distributive shock is distinctly different than the other three forms of shock because it is characterized by a loss of vascular tone. Vasodilatory shock is a general term that describes tissue hypoperfusion due to a decrease in SVR (or hypoperfusion despite a normal or elevated CO). Technically, distributive shock is a subset of vasodilatory shock characterized by maldistribution of blood flow in the microcirculation (consisting of arterioles, capillaries, and venules) or at the organ level. However, since most cases of vasodilatory shock result in distributive shock, the terms are often used interchangeably. Septic shock causes vasodilatory/distributive shock in 96% of cases, but this shock type can also be caused by several conditions, including neurogenic shock (typically secondary to acute spinal cord injury), immune-mediated (ie, anaphylactic), or nonimmunologic (ie, anaphylactoid) reactions, adrenal insufficiency, pancreatitis, acute liver failure, or as a component of ischemia-reperfusion injury (eg, after cardiopulmonary bypass or return of spontaneous circulation after cardiac arrest).

PATHOPHYSIOLOGY

Each shock syndrome has a different etiology and resultant pathophysiology. However, since all shock syndromes lead to inadequate tissue perfusion and cellular dysoxia, they have the same effect on cellular metabolism. Figure e42-1 provides a simplified view of the pathophysiology of circulatory insufficiency assuming the acute insult causing shock did not result in immediate patient death. Cell damage and death may occur from the primary insult or from ischemia-reperfusion injury. While the primary insult for shock leads to initial harm, the host response can also result in deleterious effects. Ischemia-reperfusion injury is a consequence of the host response to an abrupt decrease in tissue perfusion with subsequent restoration of perfusion, leading to a systemic inflammatory response syndrome with the release of a multitude of mediators that have complex interactions to further injury. In addition to edematous obstruction of capillaries and oxygen-free radical damage of cell membranes, several cellular (eg, white blood cells and platelets) and humoral (eg, procoagulants, anticoagulants, complement, and kinins) components are activated, causing the release of other inflammatory mediators and the formation of microthrombi. The resulting reperfusion injury may range from readily reversible organ dysfunction to multiple-organ failure and death. Cells have varying responses to hypoxia, ranging from astrocytes that quit functioning almost immediately to other cells that may tolerate more prolonged periods of hypoperfusion. Left unmitigated, cell death occurs with prolonged injury and is usually heralded by vasodilation and acidosis.

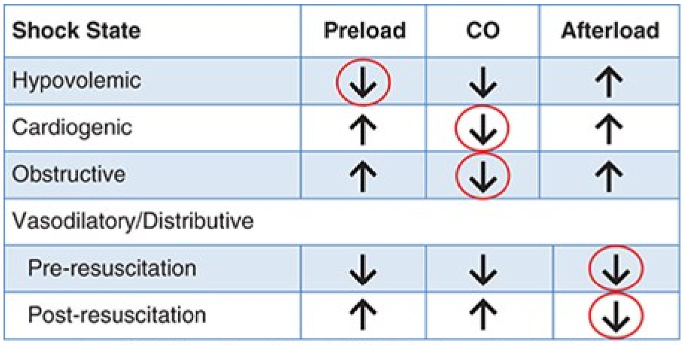
Most patients admitted to the ICU with circulatory shock have some level of systemic inflammatory response syndrome, which is the body's response to tissue injury. This syndrome is defined by several hypermetabolic changes reflected in the patient's temperature, white blood cell count and differential, and respiratory and heart rates. The stress response involves complex interactions between the nervous system and immunomodulating substances and has similar (if not the same) harmful and helpful consequences described with reperfusion following shock. As part of the stress response, anti-inflammatory pathways are also activated to counterbalance the pro-inflammatory effects on local tissues. Vagal nerve-mediated release of acetylcholine leads to suppression of pro-inflammatory cytokines by macrophages.[8] Additionally, the renin-angiotensin-aldosterone and hypothalamic-pituitary-adrenocortical systems are activated, with angiotensin II, vasopressin, and cortisol released to maintain blood pressure through vasoconstriction and concomitantly retain sodium and water in the kidneys to increase cardiac preload. Cortisol and catecholamine release from the adrenal gland also inhibit pro-inflammatory cytokine production.[8] If the underlying problems are left untreated, the patient may develop multiple-organ dysfunction syndrome during the final stages of illness.

③ Conceptually, shock syndromes can be differentiated based on the evaluation of preload, cardiac output, and afterload (Fig. e42-2).[2,9] For example, while hypovolemic and cardiogenic shocks both result in a decreased cardiac output, hypovolemic shock is caused by low cardiac preload, and cardiogenic shock results in an elevated cardiac preload. Because cardiogenic shock and obstructive shock have the same profile in this conceptual model, some experts consider the causes of an obstructive shock to be etiologies of cardiogenic shock. Vasodilatory/distributive shock is typically described as a hyperdynamic shock state from low SVR, but a high cardiac output only develops after venous return is restored (typically with fluid resuscitation).[9,10] For this reason, vasodilatory/distributive shock may be divided into two stages: pre-resuscitation and post-resuscitation.

FIGURE e42-2

Circles indicate primary dysfunction in shock state. (CO, cardiac output)



Shock State	Preload	CO	Afterload
Hypovolemic	↓	↓	↑
Cardiogenic	↑	↓	↑
Obstructive	↑	↓	↑
Vasodilatory/Distributive			
Pre-resuscitation	↓	↓	↓
Post-resuscitation	↑	↑	↓

Hypovolemic shock is extracellular volume depletion that may result from blood loss (plasma and red blood cells) due to trauma, surgery, or internal hemorrhage, or plasma loss due to fluid sequestered within the body or lost from the body. The body attempts to compensate for volume depletion beginning with autoregulatory vasoconstriction of smaller blood vessels. When the cause of circulatory insufficiency continues unabated, local mechanisms eventually fail to provide adequate compensation, and macrocirculatory changes ensue. With increasing volume depletion, blood flow to the heart (preload) is decreased, resulting in lower CO and subsequent activation of baroreceptors and chemoreceptors leading to sympathetic discharge. Also, fluid shifting from the interstitial space to the intravascular space occurs through a phenomenon known as transcapillary refill, and hormones (eg, adrenocorticotropic hormone, angiotensin, catecholamines, and vasopressin) that cause sodium and water retention by the kidneys are released. The phenomenon of transcapillary refill means that the body can have fluid losses exceeding normal plasma volume. These responses cause increases in stroke volume, heart rate, and SVR to maintain blood pressure and tissue perfusion. However, if the initial insult is significant enough, the endogenous response is overcome, and circulatory shock ensues. In the case of hemorrhage leading to hypovolemic shock (ie, hemorrhagic shock), prompt attention must be given to cellular as well as plasma losses. Red blood cells lost during the bleeding episode may compound ischemic damage in vital organs. Clotting factors and platelets are also lost in hemorrhage. The resulting bleeding problems may be aggravated by the dilutional effect of fluid resuscitation on clotting factor activity. This coagulopathy in hemorrhagic shock is typically accompanied by acidosis and hypothermia, referred to as the lethal triad.

Cardiogenic shock is inadequate CO from an intracardiac cause leading to tissue hypoperfusion. In about 80% of cases, cardiogenic shock is caused by acute myocardial infarction leading to left ventricular dysfunction.[11] Mechanical irregularities complicating acute myocardial infarction, such as acute mitral regurgitation or ventricular septal or free wall rupture may also lead to cardiogenic shock. Less frequent causes include acute-on-chronic valvular heart disease, arrhythmias, and myocarditis. Isolated right ventricular cardiogenic shock is rare and will not be discussed. In the setting of acute myocardial infarction, coronary ischemia leads to an abrupt reduction in CO, which causes a decrease in blood pressure and further impairs coronary perfusion. Sympathetic nervous system activation leads to compensatory tachycardia and vasoconstriction. While endogenous catecholamine release initially maintains blood pressure, it also increases myocardial oxygen demand, which can worsen ischemia and create a vicious cycle. As an adaptive mechanism, the left ventricle also dilates to maintain stroke volume. This leads to increased cardiac preload, pulmonary venous hypertension, and subsequent pulmonary edema. Patients with cardiogenic shock may also have cytokine-mediated vasodilation and microcirculatory dysfunction.[11]

The source of obstructive shock is an extracardiac obstruction to cardiovascular flow, which may lead to impaired diastolic filling (eg, tension pneumothorax or cardiac tamponade) or impaired systolic contraction (eg, pulmonary embolism or acute-on-chronic pulmonary hypertension). In cases where the diastolic filling is impaired, ventricular preload is decreased. However, in impaired systolic contraction, ventricular afterload is abruptly increased, leading to ventricular failure. Both etiologies of an obstructive shock lead to decreased CO and similar compensatory mechanisms as with cardiogenic shock ensue.

Vasodilatory/distributive shock is caused by systemic vasodilation. While sepsis is the most common etiology of vasodilatory/distributive shock, other causes include anaphylaxis, spinal cord injury, pancreatitis, and acute liver failure. The deficiency of vascular smooth muscle cell constriction may be from activation of vasodilatory mechanisms or a failure of vasoconstrictive pathways. In septic shock, the host response to the infecting pathogen leads to the release of proinflammatory cytokines, which activate endothelial cells to increase expression of inducible nitric oxide synthase (iNOS) resulting in NO production. Nitric oxide subsequently causes vasodilation through the cyclic guanosine monophosphate pathway. Additionally, lactate and intracellular acidosis activate adenosine triphosphate (ATP)-sensitive potassium channels, which causes potassium efflux and cellular hyperpolarization. This hyperpolarization impairs calcium influx through voltage-gated calcium channels even in the presence of vasoconstrictor ligands (eg, catecholamines, vasopressin, and angiotensin II), which impedes cellular depolarization and vasoconstriction. Consequently, the effectiveness of endogenous and exogenous vasoconstrictors is reduced. Prolonged exposure of vascular endothelial tissue to catecholamines may also promote receptor downregulation and "desensitization" to catecholamines. Systemic vasodilation causes ineffective circulating plasma volume through an increase in venous capacitance (venous pooling), which is exacerbated by the loss of intravascular volume through capillary leak.[8,10] Decreased venous return leads to decreased cardiac preload and decreased CO. Fluid resuscitation and catecholamine administration can restore effective circulating plasma volume and a high CO state ensues in the setting of low left ventricular afterload. Many patients with septic shock may also have myocardial dysfunction after fluid resuscitation through multiple mechanisms, including intramyocardial inflammation.[12,13] Furthermore, microthrombi and dysfunction of the microcirculation can lead to heterogeneous distribution of delivered oxygen and altered tissue perfusion despite macrocirculatory (eg, blood pressure and CO) goal attainment.[14]

④ Inadequate DO_2 leads to organ damage in critical illness. In normal individuals, oxygen consumption (VO_2) depends on DO_2 up to a certain critical level (VO_2 flow dependency). At this point, tissue oxygen requirements apparently are satisfied and further increases in DO_2 will not alter VO_2 (VO_2 flow independence). The point that VO_2 becomes dependent on DO_2 represents a pathologic transition from aerobic to anaerobic cellular metabolism and lactate production.[15,16] Although animal models of sepsis substantiate this relationship, studies in critically ill humans show a continuous, pathologic dependence relationship of VO_2 with DO_2. The apparent linear relationship between DO_2 and VO_2 has been questioned because both share variables, and this mathematical coupling can produce artifactual relationships between variables.[15] Inconsistent relationships between DO_2 and VO_2 are observed when VO_2 is measured independently by indirect calorimetry. While the systematic assessments of DO_2 and VO_2 and their dependence are rarely practiced, the concepts of ensuring adequate DO_2 are frequently applied. The DO_2 and VO_2 parameters are calculated as follows:

$$\begin{aligned} DO_2 &= CO \times CaO_2 \\ VO_2 &= CO \times (CaO_2 - CvO_2) \end{aligned}$$

DO2=CO×CaO2VO2=CO×(CaO2−CvO2)

where CO = cardiac output, CaO_2 = arterial oxygen content determined by hemoglobin concentration and arterial oxygen saturation, and CvO_2 = venous oxygen content determined by hemoglobin concentration and venous oxygen saturation (SvO_2).

Venous oximetry (ie, venous oxygen saturations) reflects the adequacy of tissue oxygenation.[16] SvO_2 and central venous oxygen saturation ($ScvO_2$) are the oxyhemoglobin saturation of venous blood obtained from the pulmonary artery and a central vein in the thorax, respectively, and are expressed as a percentage. When tissue oxygen demand exceeds supply, the oxygen extraction ratio (O_2ER) increases and values of SvO_2 and $ScvO_2$ are low. Rearranging the equations above shows that when hemoglobin, arterial oxygen saturation, and VO_2 are stable, SvO_2 or $ScvO_2$ values reflect CO. Thus, venous oximetry may be utilized as a surrogate for CO and can be useful to differentiate shock states. Although SvO_2 and $ScvO_2$ are not equivalent, they correlate well in most circumstances and $ScvO_2$ is a reasonable approximation of SvO_2. Generally, SvO_2 values above 70% (0.70) are considered adequate and normal. However, SvO_2 values below 50% (0.50) are low and may approach the critical O_2ER where anaerobic metabolism occurs and lactate concentrations will increase. In isolation, firm conclusions about the O_2ER cannot be made from SvO_2 values between 50% (0.50) and 70% (0.70), and other markers of tissue perfusion should be utilized to interpret values in this range. High venous oximetry values (above 80% [0.80]) can represent a high CO but may also be a poor prognostic sign indicating adequate DO_2 but the poor capacity of tissues to extract oxygen.[16]

Hemodynamic parameters obtained from monitoring devices are critical to shock syndrome identification, therapeutic intervention selection, and monitoring a patient's response to therapy. Importantly, one hemodynamic parameter cannot show the complete hemodynamic profile. Instead, hemodynamics must be interpreted in the context of multiple parameters.[1] Also, a monitoring device by itself cannot improve patient-centered outcomes and the information obtained must be combined with evidence-based therapies. The type of shock may be clear based on the patient's presenting symptoms and physical examination. For example, a patient who presents after a motor vehicle collision with frank blood loss most likely has hypovolemic shock (hemorrhagic shock subtype). However, concomitant shock states may occur, such as cardiac tamponade due to hemopericardium from chest trauma in the above example. When additional information is needed to evaluate the type of shock, echocardiography is suggested over more invasive methods (such as central venous or pulmonary artery catheters).[1] Critical care clinicians are frequently and increasingly trained to perform and evaluate transthoracic echocardiograms, which can lead to a rapid (within 5 minutes) and noninvasive diagnosis of the shock type.[14,17] A rapid assessment by cardiac echocardiography includes evaluation of left and right ventricular chamber size and function, pericardial appearance, and vena cava size with and without respiration. Additional assessments of valve structure/function and measurement of the left ventricular outflow tract velocity-time integral (which can be used to calculate stroke volume and CO) may also be performed.[2,17] Ventricular chamber size and function are the most crucial components for shock differentiation because they reflect ventricular filling and contractility, respectively.

Advanced hemodynamic monitoring may be necessary to augment the diagnosis or treatment of a patient with shock. Importantly, there is no high-level evidence to support the routine use of a central venous catheter in patients with shock. A central venous catheter placed in the internal jugular or subclavian vein may be used to measure the central venous pressure (CVP), to obtain venous samples for laboratory testing (including $ScvO_2$), and to administer drugs (including vasopressors) or fluids directly to the central circulation. A triple-lumen catheter is frequently used, whereby drugs with known incompatibility can be administered. The CVP may be used as an estimate of preload for shock state differentiation but should not be utilized as a resuscitation goal.[1,18,19] In summary, estimates or surrogates for hemodynamic parameters that may be used include ventricular size on echocardiography or CVP as estimates for preload, and SvO_2, $ScvO_2$, or ventricular contractility on echocardiography as surrogates for CO.

The general goal of therapy during initial resuscitation from shock is to achieve and maintain MAP consistently above 65 mm Hg while ensuring adequate perfusion to the critical organs.[1,2] Hemodynamic and perfusion monitoring can be categorized into two broad areas: global and regional monitoring. Global parameters, such as systemic blood pressure, venous oximetry, and lactate, assess perfusion and oxygen utilization of the entire body. Regional monitoring techniques focus on tissue-specific oxygen delivery and subsequent changes in functional indices of individual organs. These measurements include coagulation abnormalities (disseminated intravascular coagulation), altered renal and/or hepatic function, altered gastrointestinal perfusion, cool extremities, cardiac ischemia, and altered sensorium. Although none of these indices alone is a reliable indicator of adequate resuscitation, they offer immediate detection and may be prognostic of recovery when combined and defined at the level of organ function. As a result, these indices are frequently used as surrogate endpoints for the goals of resuscitation. While it is assumed that normalization of these parameters infers benefit, the clinician must first treat the patient rather than relying solely on data from continuous monitoring to guide therapy.

⑤ Blood lactate should be measured in all patients in whom shock is suspected.[1,2,20] Because lactate production is increased under anaerobic conditions, blood lactate concentration can be used as a diagnostic tool for tissue hypoperfusion.[21,22] However, not all lactate elevations are from Type A hyperlactatemia where oxygen demand exceeds supply. Type B hyperlactatemia is not related to tissue hypoxia but instead is associated with an underlying disease (eg, malignancy or sepsis), a medication-related cause (eg, epinephrine, metformin, or linezolid), or inborn errors of metabolism.[22] Increased lactate production, reduced lactate elimination (commonly termed "clearance"), or the combination of these two mechanisms may lead to hyperlactatemia. Because lactate is predominantly metabolized by the liver, patients with severe liver dysfunction may have impaired lactate elimination accentuating lactate concentration elevations in shock. Additionally, regional tissue hypoperfusion (eg, arterial thrombosis leading to critical limb ischemia or mesenteric ischemia) may also produce elevated lactate concentrations. Thus, if an elevated blood lactate concentration (>2 mmol/L) does not normalize after initial resuscitation the cause must be investigated and not assumed to be due to tissue hypoxia.

Blood pressures, CO, blood lactate, and venous oximetry parameters do not offer information about perfusion to individual organs. Organ-specific hypoxia may be evident by coagulopathy as indicated by thrombocytopenia (platelet count <100,000/µL [100×10^9/L]) and/or prolonged clotting times (international normalized ratio >1.5 or activated partial thromboplastin time at least 1.5-fold the upper limit of normal), impaired renal function, urine production (<0.5 mL/kg/hr and/or increased serum concentrations of blood urea nitrogen and creatinine), altered hepatic function (substantially increased serum concentrations of transaminases and bilirubin), altered gastrointestinal perfusion (ileus and diminished bowel sounds), cool extremities, cardiac ischemia (elevated troponin levels and electrocardiogram or echocardiography changes), pulmonary ischemia with worsening partial pressure of arterial oxygen ([PaO_2]), and altered sensorium.[1,2,8] The success of resuscitation should be based on the combination of blood pressure, organ-specific parameters of regional perfusion, and global perfusion measurements.

The microcirculation plays a key role in tissue oxygenation because it is where oxygen release occurs. Microcirculatory blood flow is often altered in patients with shock (particularly in patients with septic shock) and improvements in microcirculatory blood flow are associated with improved patient outcomes.[23] Monitoring and resuscitation strategies have typically focused on global (macrocirculatory) hemodynamics, which cannot predict microcirculatory blood flow.[24] Microcirculatory evaluations (eg, sidestream darkfield imaging of sublingual blood flow) are typically not undertaken in clinical practice because proper measurements require user experience and time to analyze the results. With technical advances, though, markers of microcirculatory perfusion may be used more commonly.

Receptor Pharmacology

Comparative receptor activities of endogenous and exogenous catecholamines, vasopressin, and angiotensin II are summarized in Table e42-1.[25–32] Endogenous catecholamines are responsible for the regulation of vascular and bronchiolar smooth muscle tone and myocardial contractility. These effects are mediated by sympathetic adrenergic receptors of the autonomic nervous system located in the vasculature, myocardium, and bronchioles. Postsynaptic adrenoceptors are located at or near the synaptic junction. These receptors can be activated by naturally circulating or exogenous catecholamines (eg, norepinephrine, epinephrine, and phenylephrine), whereas presynaptic adrenoceptors are stimulated by locally released neurotransmitters (eg, norepinephrine) and are controlled by a negative feedback mechanism.

TABLE e42-1

Adrenergic, Dopaminergic, Vasopressin, and Angiotensin Receptor Pharmacology and Organ Distribution

Effector Organ	Receptor Subtype	Physiologic Response
Heart		
Sinoatrial node	β_1, β_2, AT-1	Increased heart rate
Atria	β_1, β_2	- Increased contractility - Increased conduction velocity
Atrioventricular node	β_1, β_2, AT-1	- Increased automaticity - Increased conduction velocity
His-Purkinje system	β_1, β_2, AT-1	- Increased automaticity - Increased conduction velocity
Ventricles	- α_1, AT-1 - β_1, β_2	- Increased contractility - Increased contractility - Increased conduction velocity - Increased automaticity - Increased rate of idioventricular pacemaker cells

Arterioles		
Coronary	α_1, α_2, V1, AT-1; β_2, D1, V2 (via NO)	Constriction; dilation
Skin and mucosa	α_1, α_2, V1, AT-1	Constriction
Skeletal muscle	α_1, V1, AT-1; β_2, AT-2	Constriction; dilation
Cerebral	α_1, V1, AT-1; V2 (via NO)	Constriction (slight); dilation
Pulmonary	α_1; β_2, V2 (via NO)	Constriction; dilation
Abdominal viscera (mesentery)	α_1, V1; β_2, D1	Constriction; dilation
Renal	α_1, α_2, V1, AT-1; β_1, β_2, D1, AT-2	Constriction; dilation
Veins (systemic)	α_1, α_2; β_2	Constriction; dilation
Lungs		
Tracheal/bronchial smooth muscle	β_2	Relaxation
Bronchial glands	α_1; β_2	Decreased; increased secretion
Stomach		
Motility and tone	α_1, α_2, β_1, β_2	Decreased (usually)
Sphincter	α_1	Contraction (usually)
Secretions	α_2	Inhibition
Intestine		
Motility and tone	α_1, α_2, β_1, β_2, V_1	Decreased (usually)
Sphincters	α_1	Contraction

Secretions	α_2	Inhibition
Kidney		
Aldosterone secretion	AT-1	Increased
Renin secretion	α_1; β_1	Decreased; increased
Reabsorption of water	V2, AT-1	Increased
Sodium reabsorption and H^+ excretion	AT-1; AT-2	Increased; decreased
Skeletal muscle	β_2	Increased contractility, glyconeogenesis, potassium uptake
Liver	α_1, β_2	Glycogenolysis and gluconeogenesis
Fat cells	α_1, β_1, β_2	Lipolysis (thermogenesis)
Pituitary	V3, AT-1	Adrenocorticotropic hormone secretion
Hypothalamus	AT-1	Vasopressin secretion
Nervous	AT-1	Enhanced norepinephrine secretion
Immune		
Pro-inflammatory cytokine release, macrophage, and T-cell activation	β_2, AT-1; AT-2	Increased; decreased
Coagulation system		
	V1	Thromboxane synthesis (platelet aggregation)
	AT-1	Release of plasminogen activator inhibitor-1, platelet activation

AT, angiotensin; D, dopamine; NO, nitric oxide; V, vasopressin.

The signal transduction pathways associated with catecholamine-, vasopressin-, and angiotensin II-induced effects in the heart and blood vessels are illustrated in Fig. e42-3.[25–31] Agonists of β-adrenoceptors and dopamine (D_1) receptors stimulate adenylate cyclase by a G-protein (G_s)–dependent mechanism (Fig. e42-3, top). Adenylate cyclase generates cyclic adenosine monophosphate (cAMP) from ATP. cAMP-dependent protein kinase A, which is activated by elevations in intracellular cAMP, phosphorylates target proteins to modify cellular function. Through these mechanisms, β_1-adrenoceptor activation exerts positive inotropic and chronotropic effects in the heart, and β_2-adrenoceptor and D_1-receptor activation induce vascular smooth muscle relaxation. Agonists of α_1-adrenoceptors stimulate phospholipase C-β (PLC-β) through a G-protein (G_q)–dependent process (Fig. e42-3, bottom). PLC-β produces inositol trisphosphate and diacylglycerol from cell membrane phosphatidylinositol bisphosphate. Diacylglycerol activates protein kinase C, an enzyme that phosphorylates several key proteins (eg, extracellular signal-regulated kinases, c-Jun NH_2-terminal kinases, and mitogen-activated protein kinases) that modify cellular function (eg, hypertrophy). Inositol trisphosphate elicits the release of calcium from intracellular stores, such as the sarcoplasmic reticulum. Calcium forms a complex with calmodulin, which then activates calcium/calmodulin-dependent protein kinases (CaMK). CaMKs phosphorylate target proteins to alter cellular function. Myosin light-chain kinase is an example of a CaMK. Its action of phosphorylating myosin light chain leads to vascular smooth muscle contraction.

FIGURE e42-3

Top: Catecholamine (CCA)-induced effects mediated in heart (β_1) or vascular smooth muscle (β_2, D_1). (AC, adenylate cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; PKA, cAMP-dependent protein kinase.) Bottom: CCA (α_1), angiotensin II (AngII), and vasopressin (VP)-induced actions in vascular smooth muscle. (Ca++, calcium ion; CaMK, calcium/calmodulin-dependent protein kinase; DAG, diacylglycerol; IP_3, inositol trisphosphate; K_{ATP}, ATP-sensitive potassium channel; P, phosphorus; PIP_2, phosphatidylinositol bisphosphate; PKC, protein kinase C; PLC-β, phospholipase C-β; SR, sarcoplasmic reticulum.) These pathways have been extensively simplified, and denoted cellular effects represent one of many produced. *(Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2018. The heart contains primarily postsynaptic β_1-receptors, which cause increased rate and force of contraction when stimulated. This effect is mediated by activation of adenylate cyclase and subsequent generation and accumulation of cAMP. Stimulation of postsynaptic cardiac α_1 receptors causes a significant increase in contractility without an increase in rate, an effect mediated by PLC rather than adenylate cyclase. The increased contractility is more pronounced at lower heart rates and has a slower onset and longer duration in comparison with the β_1-mediated inotropic response.

Presynaptic α_2-adrenoceptors also are found in the heart and are activated by norepinephrine released by the sympathetic nerve itself. Their activation inhibits further norepinephrine release from the nerve terminal.

Both presynaptic and postsynaptic adrenoceptors are present in the vasculature. Postsynaptic α_1- and α_2-receptors mediate vasoconstriction, whereas postsynaptic β_2-receptors induce vasodilation. Presynaptic α_2 receptors inhibit norepinephrine release in the vasculature, also promoting vasodilation. Presynaptic β_1-adrenoceptors promote neurotransmitter release. Stimulation of peripheral D_1 receptors produces renal, coronary, and mesenteric vasodilation and a natriuretic response. Stimulation of D_2 receptors inhibits norepinephrine release from sympathetic nerve endings, sequesters prolactin, and aldosterone, and may induce nausea and vomiting. D_1- and D_2-receptor stimulation also suppresses peristalsis and may precipitate ileus.

Vasopressin-induced vasoconstriction occurs through a variety of direct and indirect mechanisms.[27–29] Stimulation of vascular vasopressin (V_1)-receptors causes vasoconstriction by receptor-coupled activation of PLC and calcium release from intracellular stores via secondary messengers similar to α_1-adrenergic stimulation (Fig. e42-3, bottom). Vasopressin also inhibits vascular potassium-sensitive ATP channels via activation of protein kinase C, indirectly leading to vasoconstriction (Fig. e42-3, bottom). V_1-receptor stimulation inhibits the actions of interleukin (IL)-1β and thereby further facilitates vasoconstriction. Vasopressin also increases the activity of adrenergic receptors. The greatest vasoconstriction occurs in the skin and soft tissue, skeletal muscle, fat tissue, pancreas, and thyroid gland. In contrast, vasopressin causes vasodilation in the cerebral, pulmonary, coronary, and selected renal vascular beds by enhancing endothelial NO release through V_1- and V_2-receptor stimulation in these tissues.[27–29] Vasopressin has minimal to no direct inotropic or chronotropic effects.

V_2 receptors located in the kidneys are responsible for the antidiuretic properties of vasopressin.[27–29] Stimulation of V_2 receptors facilitates the integration of aquaporins into the luminal cell membrane of distal tubules and collecting duct capillaries to increase permeability and thus retain intravascular volume. However, vasopressin stimulation of V_1-receptors causes vasoconstriction of renal efferent arterioles and relative vasodilation of renal afferent arterioles to increase glomerular perfusion pressure and filtration rate to enhance urine production.

Vasopressin rapidly increases serum cortisol concentration by stimulating V_3 receptors in the pituitary gland to enhance the release of adrenocorticotropic hormone (ACTH).[27–29] Cortisol helps regulate pro-inflammatory states and increases blood pressure through several mechanisms, including inhibition of iNOS to reduce NO production, reversal of adrenergic receptor desensitization, and increased intravascular volume through retention of sodium and water.

Angiotensin II also causes vasoconstriction through both direct and indirect mechanisms.[30,31] When angiotensin II binds to angiotensin (AT)-1 receptors on arterioles, a G-protein (G_q)–dependent process with PLC-β activation is initiated, which results in vasoconstriction. This is a similar mechanism to α_1-adrenoceptor- and V_1-receptor–mediated vasoconstriction. Stimulation of AT-1 receptors in the hypothalamus and pituitary also leads to vasopressin and ACTH secretion, respectively, further enhancing vasoconstriction. AT-1 receptors are also present in the kidney and lead to multiple effects, including aldosterone secretion, sodium reabsorption, and H^+ excretion. In the renal vasculature, AT-1 receptors are present on efferent renal arterioles but not afferent renal arterioles, resulting in increased glomerular filtration pressure. Coagulation factors are also affected by AT-1, with increased expression of plasminogen activator inhibitor-1 (leading to inhibition of the fibrinolytic pathway) and platelet activation.[30,31] Several immune mediators are also influenced by AT-1 stimulation, including pro-inflammatory cytokine release, and macrophage and T-cell activation. Some of the effects of AT-1 are counterbalanced by AT-2; stimulation of AT-2 receptors leads to vasodilation (including skeletal muscle and afferent renal arterioles) and anti-inflammatory activity.

Adrenoreceptor Function

Most of the work describing receptor function and associated clinical pharmacology has been performed in animal models or human volunteers. In critically ill patients with shock, derangements in adrenergic receptor activity may result in resistance to exogenously administered catecholamine.[25–28] This “desensitization” is frequently characterized by myocardial and vascular hyporesponsiveness to high dosages of inotropes and vasopressor agents. Prolonged exposure of vascular endothelial tissue to vasopressor drugs (α-adrenergic agonists) or endogenous catecholamines may promote additional receptor downregulation.[26] Increased endogenous catecholamine concentrations have been reported in endotoxemic and other critically ill patients, suggesting an acquired adrenergic receptor defect and desensitization of adrenergic receptors, and alteration in voltage-sensitive calcium channels. The problem in critically ill patients may be related to decreased receptor activity or density. However, in patients with septic shock, catecholamine concentrations are even higher, so abnormalities in adrenergic receptor function are greater, with associated reductions in the concentrations of intracellular signal transduction mediators. The worsened receptor abnormality may be explained by defects distal to the receptor site, such as uncoupling of adrenergic receptors from adenylate cyclase or PLC, or dysfunction in the regulatory G-protein unit of signal transduction pathways. Hypoxemia and acidosis may further worsen receptor adrenergic activity.

In addition to catecholamines, circulating inflammatory cytokines may be partly responsible for distal alterations.[26,28,29] Macrophage-derived IL-1β and tumor necrosis factor (TNF)-α produce impaired coupling of β-adrenoceptors to adenylate cyclase resulting in myocardial hyporesponsiveness to various vasopressors and inotropes.[14,26,29] Additionally, IL-1β and TNF-α suppress gene expression of α_1-adrenoceptors, resulting in fewer receptor proteins. Cytokine-mediated iNOS expression leads to overproduction of NO, which directly contributes to vasodilation. NO also indirectly produces vasodilation by combining with superoxide to form peroxynitrite, a highly toxic reactive species that causes endothelial dysfunction, uncoupling of α_1-adrenoceptors to PLC, and deactivation of catecholamines. The result of inflammation is a system that promotes adrenergic receptor dysfunction to limit myocardial performance and accentuate vasodilation and shock.[14,26,29] However, the clinical response to vasopressors and possibly inotropic agents is variable over time because α- and β-adrenergic receptor derangements will change with the dynamic inflammatory process.[14,20,26–29] Therefore, these drugs should be dosed to clinical endpoints and not to arbitrary maximal dosages; high dosages are frequently required.

Vasopressin, Cortisol, and Angiotensin II

Endogenous arginine vasopressin, a peptide hormone also known as antidiuretic hormone, is important for osmoregulation under normal physiologic conditions. Vasopressin is produced in the hypothalamus, stored in the posterior pituitary, and released from magnocellular neurons of the hypothalamus.[28,29] Increased serum osmolality and hypovolemia are the major stimuli for vasopressin release.[29] Other stimuli commonly associated with shock are dopamine, histamine, angiotensin II, prostaglandins, pain, hypoxia, acidosis, hypotension, hypercarbia, and α_1-adrenergic receptor stimulation. Vasopressin release is inhibited by NO, natriuretic peptides, γ-aminobutyric acid, β-adrenergic receptor stimulation, and α_2-adrenergic receptor stimulation.[29]

Normal serum vasopressin concentrations are <4 pg/mL (3.7 pmol/L).[29] Serum vasopressin concentrations are elevated with hypotension. Vasopressin response in septic shock is biphasic. During the initial hours of septic shock, serum concentrations of vasopressin are appropriately high to help maintain blood pressure and organ perfusion. Thereafter, serum vasopressin concentrations decline dramatically over the next 96 hours to physiologically normal but inappropriately low values, resulting in a state of “relative deficiency.” A similar pattern has been observed in patients with hypovolemic (hemorrhagic) shock secondary to trauma.[33] In contrast, serum vasopressin concentrations remain elevated in patients with cardiogenic shock. Administration of vasopressin at 0.01 to 0.07 units/min produces concentrations similar to those observed in early septic shock and other shock states; however, the correlation between vasopressin concentrations and blood pressure is unclear.[29] Administration of vasopressin augments the decline of inflammatory mediators and improves arterial pressure while minimizing the dosage of catecholamine vasopressors.[29,34]

The mechanism of vasopressin insufficiency in septic and hypovolemic shock is not well understood. Neurohypophyseal stores in the posterior lobe of the pituitary gland are depleted during shock, likely as a result of excessive and continuous baroreceptor stimulation that eventually exhausts the limited vasopressin secretory stores. In addition, secretion of vasopressin is inhibited by enhanced endothelial production of NO, high circulating concentrations of adrenergic agonists (both endogenous and exogenous), and tonic inhibition by stretch receptors in response to volume replacement and mechanical ventilation.[29]

As with vasopressin, during sepsis, a state of “relative adrenal insufficiency” is produced by continuous activation of the hypothalamic-pituitary-adrenal axis by IL-1β, IL-6, and TNF-α that causes depletion of cortisol in the adrenal glands.[35] Administration of corticosteroids improves arterial pressure while minimizing the dosage of catecholamine vasopressors. Proposed mechanisms of the vasoconstrictor effect of corticosteroids include increasing the number and function of α_1- and β-adrenergic receptors and attenuating the production of vasodilatory inflammatory mediators.

The use of corticosteroids for the treatment of septic shock has been a topic of controversy for many years. Interest in corticosteroid use is driven by the awareness of critical illness-related corticosteroid insufficiency.[36] Relative adrenal insufficiency, a component of critical illness-related corticosteroid insufficiency, has been defined as a random cortisol concentration <10 μg/dL (280 nmol/L) or an increase of <9 μg/dL (250 nmol/L) following a dose of synthetic ACTH irrespective of the initial serum cortisol concentration. Although absolute insufficiency is rare, relative adrenocortical insufficiency is present in 50% to 70% of patients with septic shock and is associated with a poor outcome.[36]

Conversely, an elevated random cortisol concentration (>34 μg/dL [940 nmol/L]) is also a predictor of mortality.[36] Mortality is further increased if cortisol response to ACTH is <9 μg/dL (250 nmol/L), suggesting that the risk of mortality is greatest in situations of adrenal gland "fatigue" (ie, degree of stress is not matched by sufficient cortisol production by the adrenal glands despite operating at maximal functional capacity).

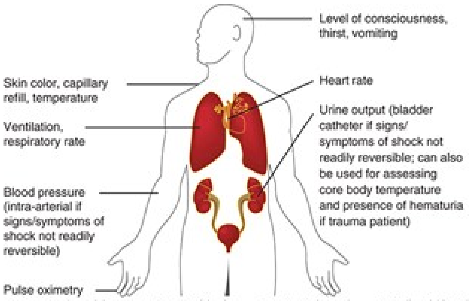
Angiotensin II concentrations may also be low in patients with vasodilatory shock resulting in a "relative deficiency." Typically, angiotensin II concentrations are elevated in patients with effective hypovolemia (ie, hypovolemic shock and vasodilatory shock) because of renin secretion. However, pro-inflammatory cytokines (eg, IL-1β and TNF-α) can lead to downregulation of AT-1, which leads to low aldosterone concentrations despite high concentrations of renin and angiotensin II.[31] Additionally, reduced sensitivity of AT-1 to angiotensin II as well as the impaired conversion of angiotensin I to angiotensin II via angiotensin-converting enzyme has been observed.[31]

CLINICAL PRESENTATION

The initial presentation of patients with circulatory shock can vary markedly. A patient's first contact with the healthcare setting is commonly a result of the underlying etiology such as fever and malaise associated with infection or chest pain associated with acute myocardial infarction. However, patients may also present with overt signs of tissue hypoperfusion. Regardless of patient age or preexisting conditions, the initial monitoring of a patient with suspected circulatory shock should include the following non-invasive parameters: vital signs, urine production, mental status, and physical examination (Fig. e42-4). Clinical manifestations of tissue hypoperfusion may be apparent at the bedside, including neurologic (eg, confusion or obtundation), cutaneous (eg, warm skin in states of vasodilation and cool, clammy, or mottled skin in states of vasoconstriction), and renal (eg, low urine production) abnormalities. However, signs of tissue hypoperfusion must be interpreted in the context of concomitant therapies (eg, sedative administration) and the patient's history (eg, chronic end-stage renal disease with anuria).

FIGURE e42-4

Clinical parameters—evaluation and monitoring of patients in shock.



Level of consciousness, thirst, vomiting
Skin color, capillary refill, temperature
Heart rate
Ventilation, respiratory rate
Urine output (bladder catheter if signs/ symptoms of shock not readily reversible; can also be used for assessing core body temperature and presence of hematuria if trauma patient)
Blood pressure (intra-arterial if signs/symptoms of shock not readily reversible)
Pulse oximetry

Although the presenting signs and symptoms of circulatory insufficiency are variable, patients usually have decreased blood pressure, increased heart and respiratory rates, and a normal or low-normal temperature (eg, 36°C–37°C [96.8°F–98.6°F]) in the absence of infection, exposure to extremes of temperature, and medications that impair thermoregulation. However, patients with infection may have an elevated temperature (eg, above 38.3°C [101°F]). As mentioned earlier, recordings of vital signs must be interpreted in light of known or suspected baseline conditions. For example, alcohol, β-blockers, diuretics, and medications with anticholinergic effects may impair thermoregulation. Medications such as β-blockers and calcium channel blockers or disease states like cirrhosis may alter resting blood pressure and heart rate, as well as the subsequent response to therapeutic interventions. Although a blood pressure of 110/70 mm Hg (systolic/diastolic) may be acceptable in many patients, it may be inadequate in a patient with preexisting hypertension who normally has a blood pressure of 170/105 mm Hg. At the other extreme, patients with low blood pressure may have inaudible or inaccurate determinations with cuff (sphygmomanometric) measurements. Chapters 1 and e29 detail blood pressure measurement (eg, cuff size and position). In this case, intra-arterial monitoring is indicated. The respiratory rate may be elevated because of anxiety or as a compensatory mechanism for the metabolic acidosis caused by lactic acidosis. Pulse or arterial oxygen saturation may be decreased because of pulmonary edema.

Mental status changes associated with circulatory shock may range from subtle fluctuations in mood or mild confusion to unconsciousness. Although the latter finding typically is indicative of more severe tissue hypoperfusion, less dramatic findings should not be interpreted as indicating the absence of shock. Similar interpretation difficulties must be considered when performing the initial physical examination. While capillary refill (rapid return of blood flow to the extremity after removal of compression) is usually impaired, an orderly progression from warm, reddish skin with appropriate capillary refill to cold, cyanotic discoloration with impaired refill may not occur.

Although the kidneys continually produce urine, the bladder stores the urine for intermittent elimination. For the initial diagnosis and management of acute circulatory insufficiency, a catheter can be inserted into the bladder for measurement of urine production. In contrast to thirst, which is a relatively insensitive indicator of volume depletion, urine production is generally diminished with inadequate kidney perfusion and increases with appropriate resuscitation. This presumes, of course, that acute kidney insufficiency or medications such as diuretics are not altering the expected response. Adults should produce at least 0.5 to 1 mL/kg/hr of urine.

Increased blood lactate concentration (above 2 mmol/L) is typically present. End organ dysfunction may be reflected in laboratory testing, such as elevated serum creatinine with renal dysfunction or elevated transaminase levels with hepatic dysfunction. The complete blood count can be variable. In the absence of infection, it may be normal. But, in septic shock, the white blood cell count is usually increased (above 12,000 cells per microliter [12 × 10^9/L]). In hemorrhagic shock, hemoglobin and hematocrit decrease over time; septic shock may lead to decreased platelet count. In shock, the prothrombin time and international normalized ratio may increase over time. Cardiac troponin concentrations may be increased in the setting of myocardial ischemia.

CLINICAL PRESENTATION: Shock Syndromes

General

- Initial presentation can vary markedly, but the symptoms are typically a result of the underlying etiology of shock.

Symptoms

- Patients may report dizziness, light-headedness, confusion, or low urine production.
- Symptoms consistent with underlying shock etiology, such as cough, fever, and malaise secondary to pneumonia or chest pain secondary to acute myocardial infarction, will be present.

Signs

- Increases in heart rate (eg, >120 beats/min) and respiratory rate (eg, >30 breaths/min)
- Low blood pressure (eg, systolic blood pressure <90 mm Hg) and low or normal body temperature (eg, 36°C–37°C [96.8°F–98.6°F]) in the absence of infection. If an infection is present body temperature may be elevated (eg, above 38.3°C [101°F]).
- Impaired capillary refill time (eg, >3 seconds)
- With severe hypoperfusion, altered mental status to the point of obtundation may be observed.

Laboratory Tests

- Blood lactate concentration is typically elevated (>2 mmol/L).
- Evidence of end-organ hypoperfusion may be present (eg, elevated serum creatinine).
- Hemoglobin and hematocrit may be decreased in a bleeding patient.
- Elevated cardiac troponin concentration will be observed with acute myocardial infarction.

Other Diagnostic Tests

- Rapid assessment by cardiac echocardiography is indicated when the shock etiology is unclear.
- Advanced hemodynamic monitoring (eg, central venous catheterization) may be needed for diagnosis or treatment.

TREATMENT

⑥ Treatment of the patient with circulatory shock can be divided into four phases, with each having different (but sometimes overlapping) goals of treatment and therapeutic strategies.[2] The first phase focuses on salvage, where a minimum perfusion pressure and CO must be obtained to ensure the patient's survival. Concomitant treatment of the underlying etiology of the shock state should occur during this phase. Some of these treatments can be lifesaving measures. Examples include surgical/interventional procedures to achieve hemostasis, initiation of antimicrobials and source control to treat sepsis, and coronary revascularization to treat acute myocardial infarction. The second phase is optimization, where the goals shift to ensuring adequate organ perfusion and DO_2. Stabilization is the third phase, where the goal is preventing (further) end-organ dysfunction. In the fourth phase of de-escalation, facilitation of patient recovery is targeted where goals include weaning (or cessation) of vasoactive medications and fluid elimination. Although this chapter focuses on the salvage and optimization phases, recognizing the phase of a patient's circulatory shock is necessary to establish treatment goals and corresponding therapeutic approaches. The desired outcome is to reduce morbidity and mortality by preventing organ damage and, to the extent possible, reverse or halt existing organ dysfunction.

General Approach to Treatment

Hospitalization is indicated for patients with circulatory insufficiency that does not readily respond to fluid resuscitation. If access to the circulatory system for administration of fluids and medication is not obtained prior to hospitalization, this should be a priority. Venous access generally is obtained during the preliminary examination process. Whenever large-volume fluid resuscitation is expected, as in cases of hemorrhagic or septic shock, at least two intravenous (IV) catheters are desirable. Because flow is a function of tubing length and catheter diameter, large-bore peripheral IV lines are preferred over longer central lines for initial resuscitation. Emergent and short-term peripheral IV administration of vasopressors may be necessary, but long-term administration of these medications via a central venous catheter is preferred. Unfortunately, vascular access in some patients may be problematic, and other routes such as intraosseous infusion may be necessary. Historically, using the intraosseous route to administer fluids and medications in the United States was mostly restricted to children with poor IV access but is increasingly used in adult patients. In the stabilization phase of circulatory shock treatment, general supportive and preventative care measures are necessary. Examples include appropriate assessment and management of pain, anxiety/agitation, delirium, immobility, sleep disturbances, nutrition, glycemic control, and thromboembolism risk.

Arterial blood pressure is the commonly used endpoint of therapy; however, restoration of adequate perfusion pressure is the primary criterion of effectiveness.[1,2,20] Profound hypotension (MAP <60 mm Hg) is associated with pressure-dependent decreases in coronary, cerebral, and renal blood flow and may rapidly produce myocardial, cerebral, and renal ischemia. Therefore, a goal MAP above 65 mm Hg is often targeted to maintain perfusion; however, patient-specific characteristics must be considered in establishing a blood pressure goal and determining an adequate perfusion response to resuscitation. Indeed, in patients aged 65 years or older with vasodilatory shock, a goal MAP of 60 to 65 mm Hg decreases vasopressor exposure without increasing adverse drug reactions.[37] In contrast, a goal MAP 80 to 85 mm Hg for patients with chronic hypertension leads to a less-frequent need for renal replacement therapy.[38] In order to limit further bleeding in patients with hemorrhagic shock, the blood pressure goal is SBP of 80 to 90 mm Hg with a restricted volume replacement strategy until major bleeding has been controlled.[1,39] If MAP or SBP remains below goal, then vasopressors should be initiated to ensure tissue perfusion.

Blood pressure is an insensitive parameter of resuscitation because it is affected by several hemodynamic variables (eg, blood pressure may be within the goal range when CO is inadequate). As such, additional resuscitation goals should be utilized to ensure end-organ perfusion and DO_2 are optimized. Adequate DO_2 can be ensured through evaluating CO, SvO_2, or $ScvO_2$. Instead of considering a specific CO, SvO_2, or $ScvO_2$ value as high or low based on absolute values, it is best to interpret these values as adequate, inadequate, or trend them relative to clinical response.[16] Adequacy is determined by concomitantly assessing markers of end-organ perfusion (eg, urine production), lactate concentrations, and capillary refill time. Targeting absolute values of DO_2 or its surrogates in isolation is not recommended.[1] Serial lactate concentrations are recommended in the early phases of shock treatment because lactate clearance and normalization correspond with improved global tissue perfusion.[1,22] Since blood lactate measurement does not require invasive hemodynamic monitoring, targeting lactate clearance or normalization is an attractive endpoint. Capillary refill time is a completely non-invasive peripheral perfusion marker that rapidly changes in response to treatment. Although controversial, compared with a resuscitation strategy targeting lactate decrease by 20% every 2 hours, incorporating capillary refill time normalization (<3 seconds; evaluated every 30 minutes until normalization) as a resuscitation goal decreases organ dysfunction and may improve mortality in patients with septic shock.[40,41]

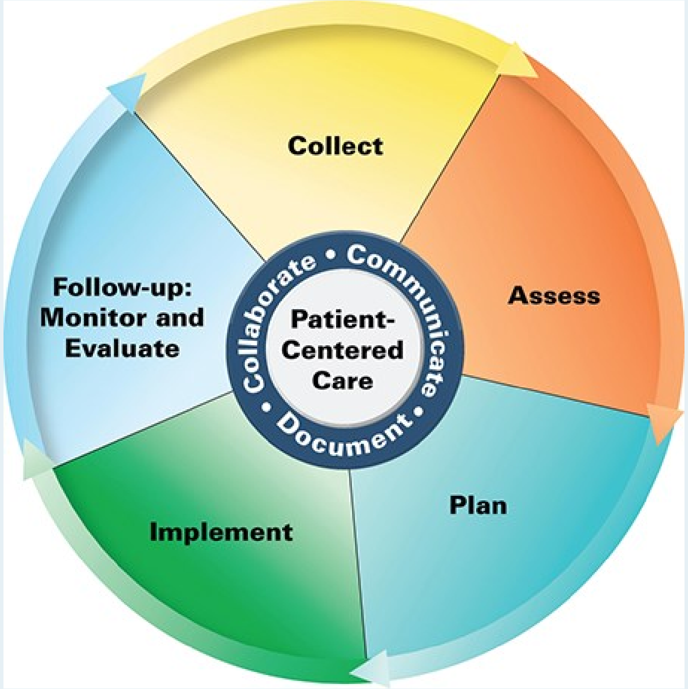
After the salvage treatment phase, fluids should only be given to patients with ineffective tissue perfusion who are predicted or demonstrated to be fluid responsive. Because only about half of hemodynamically unstable patients respond to a fluid challenge,[18,19] the benefits of fluid administration (improved CO and tissue perfusion) must be balanced against the risks of fluid overload (eg, pulmonary edema). This risk/benefit determination is informed by determining fluid responsiveness, defined as demonstration or prediction of an increase in stroke volume or CO by >10% with a rapid fluid bolus.[18,19] Importantly, blood pressure change (or lack thereof) does not reliably indicate CO response to a fluid challenge.[19] Evaluating fluid responsiveness is most crucial in patients in whom the risk of detrimental fluid effects is not acceptable (eg, a patient with refractory hypoxemia). Such patients must have evidence of hypoperfusion and a reasonable likelihood of benefitting from fluids. Although commonly used, cardiac filling pressures (eg, CVP and pulmonary artery occlusion pressure [PAOP]) poorly predict fluid responsiveness; therefore, dynamic markers of fluid responsiveness should be utilized instead.[18–20] Dynamic markers of fluid responsiveness include assessments based on heart-lung interactions in mechanically ventilated patients (eg, pulse pressure variation, stroke volume variation, and inferior vena cava dimension variation) or response to the passive leg raising test (which can be used in all patients). Each of these dynamic markers has limitations to their reliability, which should be recognized prior to their employment.[19] If fluid administration is indicated, a fluid challenge technique should be utilized where the type of fluid, rate of administration, goals to be achieved, and safety limits are outlined prior to initiation.[20,42]

Non-pharmacologic Therapy

Non-pharmacologic therapy for shock is dependent on the inciting event, although the basic life support measures such as a secure airway with appropriate oxygenation apply to all patients. For patients with hypovolemic shock, additional measures would include surgery (including stabilization of fractures and surgical control of bleeding), control of blood loss by physical compression or endoscopy, and blood component transfusion. Prevention of heat loss is also warranted since hypothermia may aggravate other problems such as coagulopathy and bleeding. For patients with heat exposure (eg, heatstroke), cooling measures are indicated. Patients with thermal injuries should have the wound sites covered with cool, moist sterile dressings until more definitive care can take place. Those with cardiogenic shock secondary to acute myocardial infarction should undergo emergent coronary revascularization and be considered for CO augmentation via a mechanical device (eg, temporary percutaneous circulatory support). Non-pharmacologic therapy is frequently the treatment of choice for obstructive shock, including pericardiocentesis or surgical evacuation of fluid for cardiac tamponade, and needle decompression and/or chest tube thoracostomy for tension pneumothorax. Surgical or catheter thrombectomy are also potential treatment options for obstructive shock secondary to pulmonary embolism. Patients with vasodilatory/distributive shock secondary to septic shock should have infectious source control and consideration should be given to fever control via external cooling. Those with immune-mediated shock should have the potentially offending agent(s) discontinued and, if possible, clearance augmented.

PATIENT CARE PROCESS

Patient Care Process for Shock Syndromes



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Reason(s) for hospitalization
- History of present illness
- Patient characteristics (eg, age, sex, pregnant)
- Past medical history

- Social history (eg, tobacco/ethanol use)
- Medication history, including intravenous fluids that have been administered
- Review of systems and physical examination findings
- Objective data (Fig. e42-4)
  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
  - Laboratory findings including lactate, hemoglobin, platelets, serum creatinine, activated partial thromboplastin time, prothrombin time
  - Capillary refill time
  - Urine production if catheterized
  - Presence of visually evident bleeding
  - Other hemodynamic or advanced monitoring data (echocardiography) if available

Assess

- Hemodynamic stability/instability (eg, systolic BP <90 mm Hg, HR >110 bpm, O_2-sat <90% [0.90])
- Non-invasive measures of circulatory insufficiency (eg, skin color, capillary refill time, and temperature; level of consciousness; urine production if catheterized)
- Dynamic markers of fluid responsiveness and advanced monitoring parameters if available
- Change in baseline organ function as evidenced by laboratory or other measures of circulatory insufficiency
- Risk for bleeding or ongoing bleeding based on objective data
- Need for vasopressors
- Type of shock syndrome (Fig. e42-2)
- Goals and wishes of patient or healthcare surrogate decision maker's goals and wishes for the patient if the patient cannot express their goals and wishes

Plan

- Surgery or procedure if needed (eg, non-compressible bleeding, coronary revascularization, and debridement of infected tissue)
- Initial focus on fluid resuscitation with type and amount of fluid based on patient-specific data (Table e42-2)
- Administer blood products as needed for hemorrhagic forms of shock (Table e42-4)
- Initiation of vasoactive medications when the patient is not responding to fluid resuscitation as is commonly seen in patients with vasodilatory/distributive forms of shock (Table e42-5)
- Temporary percutaneous mechanical circulatory support for cardiac output augmentation
- Referrals or consults to specialist providers (eg, infectious diseases providers, and hematology providers) when appropriate

Implement*

- Ensure that all members of the interprofessional care team and patient's family/friends are aware of the plan for care
- Plan for transfer to step down unit or hospital ward after stabilization in ICU

Follow-up: Monitor and Evaluate

- Ongoing signs and symptoms of circulatory insufficiency (multiple times daily) and organ function status (at least once daily)
- Presence of adverse drug reactions
- Schedule possible follow-up visit(s) based on the status upon discharge

**Collaborate with patient, caregivers, and other healthcare professionals.*

Pharmacologic Therapy

Intravenous Fluids and Blood Products

Because IV fluids are utilized as the initial treatment for most shock syndromes, they will be considered as pharmacologic agents for this discussion. The goal of administering IV fluids is to increase venous return to subsequently increase stroke volume, cardiac output, DO_2, and blood pressure. IV fluids are typically classified as crystalloids or colloids, each with advantages and disadvantages. Blood products may also be administered to replace cellular and plasma losses with the added benefit of increasing venous return. This section reviews IV fluids and blood products, the relative advantages and disadvantages of each, and provides guidance for the clinical use of these agents.

Consensus statements for the treatment of shock and hemodynamic monitoring have been published by the European Society of Intensive Care Medicine.[1] Recommendations for shock associated with trauma are available as part of the Advanced Trauma Life Support course (http://www.facs.org/trauma/atls/) and from the Eastern Association for the Surgery of Trauma.[43] Guidelines specific to the management of major bleeding and coagulopathy after trauma, and fluid therapy in neurointensive care patients are also available.[39,44] The Surviving Sepsis Campaign also has published international guidelines for the management of patients with sepsis and septic shock.[20] Other evidence relative to fluid choice for resuscitation is available from systematic reviews,[45–47] a consensus statement on colloid use in critically ill patients,[48] and a guideline pertaining to shock resuscitation in burn patients.[49] Taken as a whole, the recommendations from all of these sources are consistent in that isotonic (or near isotonic) crystalloid solutions are the initial fluid of choice for resuscitation in patients with shock and relatively large volumes should be administered (with the notable exception of patients with cardiogenic shock).

Crystalloid solutions

⑦ Isotonic crystalloid (sodium-containing) solutions are the first-line fluid of choice for forms of circulatory insufficiency that are associated with hemodynamic instability. Solutions with sodium concentrations approximating normal serum sodium values usually are indicated because they cause greater expansion of the intravascular and interstitial spaces compared with dextrose solutions (Table e42-2). Lactated Ringer's and 0.9% sodium chloride ("normal saline") solutions are examples of such crystalloid solutions. Balanced salt solutions (eg, lactated Ringer's solution and multiple electrolytes injection [eg, Plasma-Lyte A; multiple products available]) and 0.9% sodium chloride have similar efficacy in expanding plasma volume but balanced salt solutions may be safer. Excess chloride administration with infusions of 0.9% sodium chloride may lead to hyperchloremic metabolic acidosis and possibly acute kidney injury, which may be less likely to occur with balanced salt solutions. Large pragmatic, cluster-randomized, multiple-crossover studies of critically ill and non-critically ill patients suggest that balanced salt solutions are less frequently associated with major adverse kidney events within 30 days (a composite outcome of death from any cause, new renal-replacement therapy, or serum creatinine level at least 200% of the baseline level).[50,51] In these studies, the effect size of major adverse kidney events was small (about 1% absolute risk difference between groups) and no single component of the composite outcome was significantly different between groups. The study in 15,802 critically ill patients showed less renal dysfunction and numerically lower mortality (but not statistically significant) with balanced salt solutions compared to 0.9% sodium chloride, although the effects sizes were small for both outcomes.[51] Serum chloride concentrations were consistently lower and serum bicarbonate concentrations were consistently higher with balanced crystalloids over the first week of study. A large trial randomized critically ill patients to receive balanced salt solution or 0.9% sodium chloride for all fluid needs in the ICU, including fluid challenges, maintenance fluids, and drug admixtures (up to 100 mL), and found similar 90-day mortality rates.[52] Importantly, because balanced salt solutions may exacerbate cerebral edema in brain-injured patients, a pre-specified subgroup analysis was performed in patients with traumatic brain injury. This subgroup analysis found higher mortality in patients randomized to balanced salt solution; therefore, balanced salt solutions should be used with extreme caution in brain-injured patients (Table e42-3). Despite conflicting results of large trials, no study has shown the superiority of 0.9% sodium chloride over balanced salt solutions, and practice is shifting toward balanced salt solutions. Concerns have been raised relative to the administration of balanced salt solutions in patients with pre-existing hyperkalemia (because the solutions contain potassium), but these concerns have not been substantiated in clinical trials.[53]

TABLE e42-2

Fluid Distribution and Major Indications[a]

Fluid	**Intracellular**	**Interstitial**	**Intravascular**	**Major Indication**
0.9% Sodium chloride, lactated Ringer's, or multiple electrolytes (eg, Plasma-Lyte A)	None	750 mL	250 mL	Intravascular volume expansion
3% Sodium chloride	→	750 mL+	250 mL+	Small boluses (eg, 150-300 mL) and/or intermittent infusions used for patients with elevated intracranial pressure or those with symptomatic hyponatremia
5% Dextrose / 0.45% sodium chloride	333 mL	500 mL	167 mL	Maintenance fluid in euvolemic or dehydrated (sodium and water loss) patients with mild signs/symptoms of volume depletion
5% Dextrose	667 mL	250 mL	83 mL	Dehydration (primarily water loss) in patients with mild signs/symptoms of volume depletion
5% Albumin	None	None	1,000 mL[b]	Intravascular volume expansion
25% Albumin	→	→	1,000 mL+++[b]	Given by intermittent infusion to expand the intravascular volume via recruitment of volume from the interstitial space (eg, after large-volume paracentesis)

[a] Based on the administration of 1 L of each solution *for comparative purposes only*. This amount of fluid, particularly for 3% saline and 25% albumin, would be inappropriate and likely harmful if given over a short period of time. Numbers are approximations and are likely not reflective of actual fluid distribution in critically ill patients; arrows indicate the direction of fluid shift and plus signs indicate fluid pulled from other compartments.

[b] After distribution and attainment of steady-state conditions, 60% of albumin (and associated fluid) is in the interstitial compartment and 40% is in the intravascular compartment.

TABLE e42-3

Adverse Effects of Plasma Expanders

Balanced salt solutions (lactated Ringer's or multiple electrolytes [eg, Plasma-Lyte A])

- Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy)
- Hyponatremia with lactated Ringer's (has 130 mEq/L [mmol/L] of sodium); because multiple electrolytes (eg, Plasma-Lyte A) has 140 mEq/L (mmol/L) of sodium, this is not a concern with this solution

0.9% Sodium chloride ("normal saline")

- Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy)
- Hyperchloremic metabolic acidosis (contains 154 mEq/L [mmol/L] of chloride)
- Hypernatremia (contains 154 mEq/L [mmol/L] of sodium)
- Acute kidney injury (from hyperchloremia)

3% Sodium chloride ("hypertonic saline")

- Primarily extensions of pharmacologic actions (eg, fluid overload, dilutional coagulopathy, and intracellular volume depletion)
- Hypernatremia (contains 513 mEq/L [mmol/L] of sodium)
- Hyperchloremia (contains 513 mEq/L [mmol/L] of chloride)

Albumin

- Primarily extensions of pharmacologic actions (eg, fluid overload; dilutional coagulopathy)
- Amino acid profile and catabolism alterations (clinical significance?); potential protein overload if given with exogenous protein (eg, parenteral nutrition)
- Anaphylactoid/anaphylaxis reactions (life-threatening reactions rare; higher in patients with immunoglobulin A deficiency)
- Interactions with medications and nutrients (clinical significance varies)
- Renal dysfunction with hyperoncotic albumin

Although lactated Ringer's solution contains lactate, it does not cause substantial elevations in circulating lactate concentrations when used as a resuscitation solution.[54] Once adequate plasma volume has been restored by fluid administration, the body can readily clear the blood of the excess lactate that has accumulated from both anaerobic metabolism and lactated Ringer's solution. However, blood samples for lactate determinations drawn through catheters (arterial and venous) that have not been cleared appropriately may have spurious increases or decreases in lactate concentrations because of retained lactated Ringer's and nonlactated solutions (eg, varying concentrations of dextrose-in-water or sodium chloride), respectively. Therefore, blood samples for lactate concentration determinations should be drawn from a catheter that has been cleared adequately (eg, 5 mL) of infusate after temporarily stopping the fluid infusion.

Alternative Fluid Treatments

Hypertonic sodium chloride solutions have been studied as alternatives to isotonic crystalloid solutions for hypovolemic shock, particularly in patients with traumatic brain injuries. By causing redistribution (ie, pulling fluid) from the intracellular space, hypertonic solutions cause rapid expansion of the intravascular compartment, which is essential for vital organ perfusion. In head-injured patients, it has been postulated that this redistribution should decrease intracranial pressure because the vessels of the brain are more impermeable to sodium ions than are vessels in other areas of the body. Additionally, hypertonic sodium chloride solutions have beneficial immunomodulating actions when compared with more isotonic solutions in experiments with animals. Unfortunately, the theoretical benefits associated with hypertonic sodium chloride solutions have not translated into improved outcomes when used for the initial resuscitation of patients with shock.

From a safety standpoint, hypertonic sodium chloride is a high-risk concentrated electrolyte solution. Potential dosing and administration errors and related adverse events can occur when hypertonic sodium solution is ordered and administered by clinicians relatively unfamiliar with its use. Potential adverse events include cellular crenation and damage caused by the dramatic fluid shifts associated with hypernatremia, metabolic acidosis from hyperchloremia, and peripheral vein destruction from high osmolality. The osmolarity of 3% sodium chloride is 1,026 mOsm/L. Although there are some notable exceptions (eg, peripheral parenteral nutrition solutions often approach 1,000 mOsm/L), IV solutions with osmolarity values above 600 mOsm/L are usually recommended to be administered through a central line. In the limited number of studies conducted in humans to date, adverse effects have been uncommon with short-term administration of hypertonic (2-3%) sodium solutions administered through a peripheral line.

Larger-molecular-weight solutions (ie, >30,000 Da) known as *colloids* have been recommended in conjunction with or as replacements for crystalloid solutions, although their use is controversial.[20] The major theoretical advantage of these compounds is their prolonged intravascular retention time compared with crystalloid solutions. In contrast to isotonic crystalloid solutions that have substantial interstitial distribution within minutes of IV administration, colloids remain in the intravascular space for hours or days, depending on factors such as the size of the colloid molecules and capillary permeability. Examples of colloids used as plasma expanders in the United States include albumin, hydroxyethyl starch, and much less commonly, dextran. In the absence of increased capillary permeability, the theoretical benefit of colloids over crystalloids is that their increased molecular weight increases intravascular oncotic pressure, leading to enhanced intravascular volume expansion and longer retention time.

However, even in patients with intact capillary permeability, small and intermediate size colloid molecules, such as albumin, eventually leak through capillary membranes, with a few notable exceptions (eg, those in the central nervous system and glomeruli). In the case of albumin with a distribution half-life of 15 hours in normal subjects, approximately 60% of administered albumin molecules (and associated fluid) shifts to the interstitial space within 3 to 5 days of exogenous administration. In patients with altered vascular permeability (eg, sepsis), the leakage of albumin from the intravascular to the interstitial space may occur within hours, not days. The primary adverse effect concern of all colloids is fluid overload, which is an extension of their pharmacologic action. Excessive fluid administration has been shown to increase capillary permeability through disruption of the endothelial glycocalyx. Another adverse effect of increasing concern is renal dysfunction that seems to be related to hyperoncotic (eg, 25%) albumin and other starch and dextran products. The mechanism of this adverse effect may be related to alteration of normal glomerular oncotic pressure differences or formation of lesions in the kidney.[55]

Albumin is available in the United States in 5% and 25% concentrations. Plasma protein fraction has oncotic actions similar to a 5% albumin solution, which is not surprising because albumin is the predominant protein in this product. When given in equipotent amounts, albumin is much more costly than crystalloid solutions. Additionally, the 5% and 25% albumin solutions typically are priced such that no cost savings are associated with dilution of the 25% product to make a 5% concentration. Dilution should be avoided because of the possibility of preparation errors. Hemolysis and death have occurred when 25% albumin was inappropriately diluted with sterile water for injection, due to a dramatic lowering of effective osmolarity.[56] The 5% albumin solution is relatively *iso-oncotic*, which means that it does not pull fluid into the compartment in which it is contained. In contrast, 25% albumin is referred to as *hyperoncotic* albumin, because it tends to pull fluid into the compartment containing the albumin molecules. In general, the 5% albumin solution is used for shock states with inadequate venous return. The 25% solution should not be used for acute circulatory insufficiency unless it is used in combination with other fluids or it is being used in patients with excess total body water but intravascular depletion as a means of pulling fluid into the intravascular space. An example of the latter condition is cirrhosis with ascites in which total body water is substantially increased, but the patient is hypotensive because of a lack of intravascular volume. For this approach to be cost-effective, one must presume that excess water (eg, interstitial fluid accumulation in the lungs) is associated with adverse effects, and albumin remains in the intravascular space long enough to be beneficial. Albumin has a variety of functions beyond plasma expansion, such as binding properties, inflammatory gene modification, and antioxidant and free radical scavenging effects, which have been used to justify its administration instead of less-expensive crystalloid or other colloid products. Although appealing theoretically, improved patient outcomes related to these properties have not been documented in sufficiently powered, randomized controlled trials. Additionally, the clinician must realize that the properties of commercially available albumin products are not biologically identical to those of native albumin. For example, denaturation of the products may lead to inefficient binding and decreased oncotic activity.

From a historical perspective, the so-called crystalloid versus colloid debate was intensified when a meta-analysis found an overall increase in mortality associated with albumin using pooled results of randomized investigations.[57] With the notable exception of trauma patients, a subsequent and more comprehensive systematic review did not find increased mortality attributable to albumin.[58] These conflicting findings prompted the design and completion of a landmark investigation in critically ill patients, which did not detect a statistically significant difference in 28-day mortality between patients treated with 0.9% sodium chloride or 4% albumin.[59] In a subset of patients with severe traumatic brain injury, mortality in those receiving albumin was significantly higher at 24 months, an effect that seemed to be confined to patients with severe injury.[60] This multicenter, randomized, double-blind investigation, the Saline versus Albumin Fluid Evaluation (SAFE) study, involved a heterogeneous group of ICU patients and was not sufficiently powered to look at various subsets. So clinicians must be cautious when extrapolating the results to more specific patient populations.

Additionally, the assigned study fluid was used throughout the 28-day study period for volume expansion; therefore, this study was not exclusively an evaluation of the initial phase of fluid resuscitation and the implications of the study findings in that setting are unclear. The results of meta-analyses that include this large study are conflicting with regard to a survival benefit associated with colloid administration; however, they are in agreement that resuscitation with albumin achieves higher values of CVP and MAP more rapidly than crystalloid fluids with a lower overall fluid balance.[61–64] A randomized study of patients with sepsis also showed that albumin 20% achieved higher MAP despite a lower net fluid balance compared to crystalloid solutions but mortality rates were similar.[65]

Colloids are expensive solutions and whether these beneficial outcomes confer cost-benefit over crystalloids has not been established. While the use of albumin in specific patient populations (eg, septic shock) is still debated, a systematic review and meta-analysis found that when compared with alternative resuscitation solutions, hydroxyethyl starch was associated with increased mortality, increased acute kidney injury, and increased use of renal replacement therapy.[66] In light of these studies, US product labeling of all medications in the class was changed to state they are contraindicated in critically ill patients; therefore, starch products should not be used for fluid resuscitation.

Blood Products

In the case of a patient with hemorrhage, prompt attention must be given to cellular as well as plasma losses. Red blood cells lost during the bleeding episode may lead to ischemic damage in vital organs. Packed red blood cell transfusions may be needed to increase the oxygen-carrying capacity of the blood because oxygen transport is a function not only of CO but also of hemoglobin concentration and saturation, and of hemoglobin affinity for oxygen. Red blood cells contain hemoglobin that delivers oxygen to tissues. Neither crystalloids nor colloids perform this function. Although a small group of trauma patients respond to the initial fluid bolus and remain stable, most patients respond initially and then deteriorate. The latter patients, as well as patients with blood loss associated with surgery and those with gastrointestinal hemorrhage, frequently need blood components such as packed red blood cells (Table e42-4).

TABLE e42-4

General Indications and Concerns for Blood Products and Prothrombin Complex Concentrates[a]

Product	Major Indication	Major Concerns
Packed red blood cells	Increase oxygen-carrying capacity of blood. Usually indicated in patients with continued deterioration after volume replacement or obvious exsanguination	Hypocalcemia, hyperkalemia, hyperphosphatemia, circulatory overload, ARDS (lowest risk among blood products), immunomodulation, transfusion reactions, hypothermia, and virus transmission
Fresh frozen plasma	Replacement of clotting factors. Overused; indicated if ongoing hemorrhage in patients with PT/PTT >1.5 times normal, prolonged initial fibrin formation (R value) on viscoelastic testing, severe hepatic disease, or other bleeding diathesis	Hypocalcemia, circulatory overload, ARDS (highest risk among blood products, particularly transfusions from female donors), immunomodulation, transfusion reactions, hypothermia, and virus transmission
Platelets	Used for bleeding due to severe thrombocytopenia (ie, platelet count <20,000/μL [20 × 10^9/L]), rapidly dropping platelet counts as would occur with massive bleeding, or decreased clot strength (maximum amplitude value) on viscoelastic testing	Hypocalcemia, circulatory overload, ARDS, immunomodulation, transfusion reactions, hypothermia, and virus transmission
Cryoprecipitate	Contains concentrated fibrinogen, von Willebrand factor, factor VIII, and factor XIII. Not indicated in acute hemorrhage but rather used after specific deficiencies are identified (eg, decreased rate of clot formation [alpha value] on viscoelastic testing)	Hypocalcemia, circulatory overload, ARDS, immunomodulation, transfusion reactions, hypothermia, and virus transmission
Prothrombin complex concentrates (PCCs)	The most commonly used product contains inactivated factors II, VII, IX, and X, and Proteins C and S. Another product contains activate factors. Used for reversal of antithrombotic agents in the setting of acute major bleeding or prior to urgent surgery/invasive procedure.	Thrombosis (arterial and venous), anaphylactic reactions, and viral transmission. Some products contain heparin and should not be given to patients with heparin-induced thrombocytopenia

ARDS, acute respiratory distress syndrome; PT, prothrombin time; PTT, partial thromboplastin time.

[a] Although whole blood can be used for large-volume blood loss, most hospitals use component therapy, and use crystalloids or colloids for plasma expansion.

Administration of excessive blood products may be counterproductive. In the case of red blood cells, attempts to raise the hemoglobin to high-normal or supranormal concentrations may decrease oxygen delivery by increasing blood viscosity. Stored red blood cells undergo biochemical alterations to reduce oxygen dissociation at the tissue level which may explain why studies do not demonstrate increased end-organ DO_2. Additionally, there are concerns of hyperkalemia, hyperphosphatemia, and immunomodulation with red blood cell administration. Many institutions curtailed a more liberal transfusion strategy (transfusion threshold less than 10 g/dL [100 g/L; 6.21 mmol/L]) following the publication of a randomized, multicenter trial of critically ill patients that found 30-day mortality to be similar between this strategy and the use of a lower hemoglobin concentration threshold for transfusion (less than 7 g/dL [70 g/L]; 4.34 mmol/L).[67] Although the investigators were cautious about extrapolating the results of this investigation, subsequent studies performed in patients with acute upper gastrointestinal hemorrhage, septic shock, and those undergoing cardiac surgery found similar results with a restrictive transfusion strategy (transfusion threshold of hemoglobin concentration ≤7 g/dL [70 g/L; 4.34 mmol/L]).[68–70] In fact, liberal transfusion strategies were associated with increased bleeding in patients with acute upper gastrointestinal hemorrhage and higher mortality in critically ill patients with lower severity of illness. Furthermore, even in patients with acute myocardial infarction, a transfusion threshold hemoglobin concentration ≤8 g/dL (80 g/L; 4.97 mmol/L) was non-inferior to a transfusion threshold hemoglobin concentration ≤10 g/dL (100 g/L; 6.21 mmol/L) in preventing major adverse cardiac events at 30 days.[71] With the exception of the critically ill or perioperative patients with acute exsanguination, there is little justification for a liberal transfusion strategy based solely on hemoglobin concentrations.

Clotting factors may be lost from bleeding or consumed through hemostatic mechanisms requiring replacement. Laboratory parameters or viscoelastic testing (eg, thromboelastography) may guide blood product administration.[39] Blood products that contain clotting factors include fresh frozen plasma, platelets, and cryoprecipitate (Table e42-4). Concentrated products available as a lyophilized powder for reconstitution (eg, prothrombin complex concentrates or fibrinogen concentrate) are increasingly used as alternatives to traditional blood products because they are not associated with hypervolemia or immunomodulation. However, they may enhance the risk of thromboembolic events. Reversal agents for antithrombotic-associated bleeding may also be administered (eg, prothrombin complex concentrates for warfarin, idarucizumab for dabigatran, and andexanet alfa for factor Xa inhibitors).

Blood products have risks beyond immunomodulation. There is a rare but important risk of virus transmission (eg, human immunodeficiency virus and hepatitis). Citrate that is added to stored blood products to prevent coagulation may bind to calcium, resulting in hypocalcemia. In patients receiving large amounts of blood products, prophylactic calcium administration may be warranted until levels are available. Potassium and phosphate concentrations often are elevated in stored packed red blood cells, particularly when hemolysis has occurred during storage. Additionally, blood product administration may be associated with acute respiratory distress syndrome (particularly with fresh frozen plasma and platelets) or circulatory overload. Other issues that must be considered with blood product administration include monitoring for transfusion-related reactions and attention to appropriate warming, particularly when large volumes are given to pediatric patients because hypothermia is associated with increased fluid requirements and mortality.

Fluid Resuscitation in Distributive (Septic) Shock

In patients with distributive shock, the initial fluid challenge volume is unclear. While the Surviving Sepsis Campaign guidelines suggest 30 mL/kg crystalloids given within the first 3 hours of shock recognition, the evidence to support this specific volume for administration is low quality.[20] Multiple approaches exist for fluid resuscitation during the first 6 hours of therapy. One initial approach includes liberal fluid administration (50-75 mL/kg) while reserving vasopressors, and another approach includes relatively restrictive initial fluid administration (≤30 mL/kg) with earlier use of vasopressors to maintain tissue perfusion. Both approaches have rational because early aggressive fluid resuscitation can restore effective venous return (and thus increase cardiac output) but can also contribute to edema within organs that impairs their function. A comparison of these initial resuscitation approaches is ongoing.[72] Greater than 30 mL/kg of crystalloid fluids in total may be needed to obtain goal MAP, reverse global hypoperfusion (lactate clearance, $ScvO_2$ ≥70% [0.70]), or achieve clinical indication of regional organ-specific perfusion (eg, urine production). An isolated bolus (eg, 250-500 mL) in an adult patient with shock is unlikely to cause a substantial change in blood pressure or acid-base balance. Therefore, multiple fluid boluses are often needed in such patients to achieve hemodynamic stability. However, excessive fluid administration has been associated with higher mortality and overly aggressive fluid administration should be avoided, especially in patients with heart failure or impending pulmonary edema.[55] Also, IV medication diluents can contribute significantly to total fluid volume administration during a patient's ICU stay and, when 0.9% sodium chloride is utilized, can contribute to hyperchloremia and possibly acute kidney injury.[73] Therefore, total fluid administration should be accounted for, and dynamic fluid response with clinical assessment should occur frequently following each fluid challenge.[20]

Fluid Resuscitation in Hypovolemic (Hemorrhagic/Traumatic) Shock

The need for immediate treatment of hemorrhagic shock with plasma expanders (ie, crystalloids or colloids) seems obvious, but no large, well-controlled trials conducted in humans have supported this practice. To the contrary, fluid resuscitation beyond minimal levels (ie, mean arterial pressure ≥60 mm Hg) is harmful in patients with penetrating abdominal trauma due to hemodilution and clot destabilization. One prospective study of adult patients with gunshot or stab wound injuries to the torso and an SBP of 90 mm Hg or less found that delayed fluid resuscitation until the operation was associated with increased survival and discharge from the hospital.[74] Since concerns were expressed about the comparability of the immediate and delayed resuscitation groups, particularly because true randomization did not take place, a follow-up randomized trial was conducted to verify the findings. There were no differences in survival (four deaths in each group) in the second trial regardless of whether systolic blood pressure was titrated to ≥100 mm Hg or 70 mm Hg.[75] Both studies were conducted in populated urban areas with approximately 2 hours from the time of injury to operation. Therefore, the results may not be applicable to rural areas with extended transport times. There also is a concern in applying the results of these investigations to patients with certain kinds of single-system injuries, particularly head trauma, where cerebral perfusion pressure is of primary importance.

The administration of hypertonic sodium chloride solutions requires less overall fluid than isotonic solutions; therefore, it stands to reason those concerns regarding the dilutional effect of isotonic solutions could be minimized with hypertonic saline solutions. In order to address ongoing questions of efficacy, hypertonic sodium chloride solutions with or without a colloid (ie, 7.5% sodium chloride or 7.5% sodium chloride in 6% dextran

70) for prehospitalized trauma patients with shock and traumatic brain injury were evaluated in two trials conducted by a network of sites known as the Resuscitation Outcomes Consortium. Both the parallel trials were stopped when it was determined that the hypertonic sodium chloride solutions were no better than 0.9% sodium chloride (“normal saline”) and further enrollment would not change the outcomes.[76,77] Therefore, isotonic crystalloids are the fluid of choice since they are equal in efficacy with a lower risk of adverse effects compared with hypertonic solutions that are high-risk electrolyte solutions. Balanced salts solutions may be used as an alternative solution to 0.9% sodium chloride but should be avoided in patients with severe traumatic brain injury because it may worsen cerebral edema.[39] Given their relatively poor intravascular expansion and association with poor outcome in animal models of closed head injury, hypotonic solutions should be avoided in this population.

Although the applicability of the aforementioned studies to other populations and settings is debatable, the *presumption* of benefits from immediate plasma expansion in all preoperative patients with circulatory insufficiency caused by hemorrhage is no longer valid. Instead, the initial priority should be surgical control of the bleeding source. Until this is possible, fluids should be given in small aliquots to yield a palpable pulse and to maintain MAP no more than 60 mm Hg and SBP no more than 90 mm Hg based on accurate measurements (eg, arterial monitoring). Approaches also should be used to avoid or decrease acute traumatic coagulopathy, which is the result of the combination of bleeding-induced shock, tissue injury-related thrombin-thrombomodulin-complex generation, and activation of anticoagulant and fibrinolytic pathways.[39]

The periodic shortages, high costs, and adverse effects related to blood products have prompted investigations of alternative “bloodless” strategies. In addition to the use of more restrictive transfusion thresholds, as mentioned previously, these strategies have included hemoglobin-based oxygen carriers and perfluorocarbon compounds to deliver oxygen to tissues. Other strategies have aimed at reducing blood loss using improved procedural and surgical techniques, as well as the administration of hemostatic medications. Reversal of antithrombotic agents (eg, prothrombin complex concentrates for patients receiving warfarin) should be considered in the context of the patient’s degree of bleeding or operative plan and their indication for antithrombotic therapy. However, the only hemostatic medication with a proven mortality benefit is the antifibrinolytic agent tranexamic acid. The best evidence for efficacy was data from a multicenter trial involving adult trauma patients with significant bleeding (or risk for significant bleeding) who were randomized to IV tranexamic acid 1 g over 10 minutes followed by 1 g over 8 hours by infusion or matching placebo within 8 hours of injury.[78] There was a significant reduction in all-cause mortality with tranexamic acid compared with placebo with no increase in vascular or other adverse events. A more in-depth review of the results of this trial suggests that the beneficial effects are most likely to occur if tranexamic acid is given within the first 3 hours of injury. In a subsequent trial of patients with traumatic brain injury, the same tranexamic acid dosing strategy given within 3 hours of injury reduced head injury-related death within 28 days in patients with a mild-to-moderate head injury, but not in patients with a severe head injury.[79] These studies are relatively unique in that an intervention other than surgery and blood product administration reduced mortality.

In the bleeding patient, once hemostasis has been achieved, a more restrictive transfusion strategy (ie, transfusion if hemoglobin ≤7 g/dL [70 g/L; 4.34 mmol/L]) is indicated.[39] Additional blood product administration should be guided by laboratory parameters (eg, PT/INR and platelets) or viscoelastic testing (eg, thromboelastography).[39] Reversal of antithrombotic therapy (eg, prothrombin complex concentrates for warfarin) may also be utilized for severe bleeding.

Vasopressors and Inotropes

⑧ Vasopressors and inotropes are required in patients with shock when volume resuscitation is not indicated or fails to maintain adequate blood pressure (MAP ≥65 mm Hg) and organs and tissues remain hypoperfused.[1,2,8,20,27] In addition, vasopressors may be needed temporarily to treat life-threatening hypotension when tissue perfusion is inadequate despite ongoing aggressive fluid resuscitation. Inotropes are frequently used to optimize DO_2 in cases of septic shock and cardiac function in cases of cardiogenic shock.[1,2,11,20] The clinician must decide on the choice of agent, therapeutic endpoints, and safe and effective doses of vasopressors and inotropes to be used. This section provides guidance for the clinical use of adrenergic agents, optimization of pharmacotherapeutic outcomes, and minimization of adverse drug reactions in critically ill patients. Vasopressin, angiotensin II, and corticosteroids, as they relate to shock, also are emphasized because they have pharmacologic interactions with catecholamine vasopressors, possess hemodynamic effects, and are frequently used.

⑨ The choice of a particular vasopressor or inotrope agent depends on the underlying shock pathophysiology, goals of therapy, and clinical pharmacology of the agent(s).[27] Table e42-5 lists receptor selectivity, typical dosage ranges, and potential adverse drug reactions of commonly used vasopressors and inotropes.[26–29,80]In most shock syndromes, limited literature exists to guide optimal agent selection. Dosages for norepinephrine,

epinephrine, and phenylephrine may be weight based (µg/kg/min) or non-weight based (µg/min). Although controversial, there does not appear to be an effectiveness or safety difference between these dosage strategies.[81] The dosage strategy utilized is typically based on institutional preference. Only dopamine and dobutamine are commercially available as premixed ready-to-use solutions that can be stored in automated dispensing systems for rapid initiation. The use of other vasopressors and inotropes requires preparation time. Institutions may stock compounded admixtures in preparation for administration but they must follow sterile compounding and storage regulations.

Catecholamine vasopressors may result in adverse peripheral vasoconstrictive, metabolic, and arrhythmogenic effects that limit or outweigh their positive effects on the central circulation.[26–29] Excessive peripheral vasoconstriction with catecholamine vasopressors may cause ischemia or necrosis of already poorly perfused tissues, such as the skin and the mesenteric and splanchnic circulations. Some of these profound vasoconstrictive effects may be compounded by under-resuscitation with fluid administration prior to initiating the vasopressor. Vasopressor catecholamines also have the potential to cause extravasation-associated tissue damage if infusions infiltrate during peripheral administration. In the event of infiltration, an α-receptor antagonist such as phentolamine (5 or 10 mg in 10 mL saline) should be injected intradermally or nitroglycerin paste applied topically to reverse local vasoconstriction. β_1 cardiac stimulation may produce myocardial ischemia and atrial and ventricular arrhythmias, especially in patients with coronary artery disease, atherosclerosis, cardiomyopathies, left ventricular hypertrophy, congestive heart failure, or underlying dysrhythmias. All catecholamine vasopressors, especially epinephrine, stimulate β2-adrenergic receptors on immune cells, leading to immunomodulatory actions. Catecholamines inhibit the production of inflammatory cytokines (eg, IL-6, TNF-α), may enhance anti-inflammatory cytokines (eg, IL-4 and IL-10), suppress oxygen-free radical production from neutrophils, and direct proapoptotic effects. These anti-inflammatory effects may be either beneficial (by dampening harmful effects of oxygen-free radical-mediated tissue injury) or deleterious (by reducing neutrophilic defense against bacteria). While epinephrine is most associated with these immunomodulatory effects, the clinical significance of these actions remains unknown.

Clinical Pharmacology and Pharmacodynamic Effects

Norepinephrine

Norepinephrine has combined strong α_1-activity and less potent β_1-agonist effects while maintaining weak vasodilatory effects of β_2-receptor stimulation. It produces vasoconstriction primarily via its more prominent α-effects on all vascular beds, thus increasing SVR.[26–28,80] Norepinephrine administration produces a small (10%-15%) increase in stroke volume.[27] Several meta-analyses have demonstrated improved MAP and mortality in ICU patients with severe hypotension treated with norepinephrine either as first-line therapy or after therapeutic failure with fluid resuscitation treatment.[1,20,80,82]

Norepinephrine 0.05 to 2 µg/kg/min reliably and predictably improves hemodynamic parameters to “normal” values in most patients with shock. As with other vasopressors, norepinephrine dosages exceeding those recommended by most references are frequently needed in critically ill patients with shock to achieve goals. A significant increase in MAP is caused by an increase in SVR. Heart rate generally decreases with norepinephrine because of reflex bradycardia from increased SVR.[26–28,80] Increasing norepinephrine doses may increase heart rate, cardiac index, DO_2, and cutaneous blood flow but these results are inconsistent. Older patients may benefit from the combined α- and β-adrenergic effects of norepinephrine, given the higher prevalence of coronary disease and compromised ventricles in this patient population. By virtue of restored MAP and hence coronary perfusion, the cardiac index is increased in older patients, whereas in younger patients with less coronary artery disease and a higher cardiac index at baseline, norepinephrine acts primarily as a vasoconstrictor. Norepinephrine can increase cardiac filling pressures (eg, CVP) by increasing venous return through vasoconstriction, but this effect is inconsistent.[83–85]

The effect of norepinephrine on oxygen transport parameters is variable and depends on baseline values and concurrently administered vasoactive agents. In most studies of norepinephrine alone, either an increase or no change in DO_2 is seen with no change in O_2ER, particularly when DO_2 values were “supranormal” prior to therapy. Splanchnic blood flow and fractional blood flow are higher with norepinephrine than dopamine or epinephrine despite higher CO with the two latter agents.

Epinephrine

Epinephrine exerts combined α- and β-agonist effects.[26–28,82] At low dosages (0.01-0.05 µg/kg/min), β-adrenergic effects predominate with an increase in stroke volume and CO. For this reason, low dosages of epinephrine may be utilized as an inotrope after cardiac surgery. When higher epinephrine dosages are used α-adrenergic effects are predominantly observed and SVR and MAP are increased. Epinephrine is an acceptable choice for hemodynamic support for patients with shock because of its combined vasoconstrictor and inotropic effects.[26–28,82,86] It is as effective as norepinephrine for MAP response in vasodilatory/distributive shock. Epinephrine dosages of 0.04 to 1 µg/kg/min alone increase hemodynamic and oxygen transport variables to "supranormal" values in shock patients without coronary artery disease. Large dosages (0.5-3 µg/kg/min) often are required, particularly for patients with septic shock. Smaller dosages (0.1-0.5 µg/kg/min) are effective when epinephrine is added to other vasopressors and inotropes. In addition, younger patients respond better to epinephrine, possibly due to greater β-adrenergic reactivity.

Despite a linear dose-response curve with rapid improvement of hemodynamic variables and DO_2, epinephrine has deleterious effects on regional hemodynamics and oxygen utilization. Although DO_2 increases mainly as a function of increases in the CO, a more variable increase in SVR is observed, VO_2 may not increase, and O_2ER may fall. A decrease in gastric mucosal perfusion may be seen during epinephrine administration but this effect can be counteracted in part by dobutamine. This may be explained by the vasodilatory effect of dobutamine on gastric mucosal microcirculation resulting in a redistribution of blood flow toward the mucosa. When compared with a combination of norepinephrine and dobutamine, epinephrine preferentially decreases splanchnic DO_2 without increasing VO_2. The effects of epinephrine on absolute and fractional splanchnic blood flow are more pronounced during severe shock. However, epinephrine, in contrast to dopamine, increases the proportion of total CO delivered to the splanchnic circulation, although VO_2 is not increased sufficiently. As a result, O_2ER values are usually lower with epinephrine than with other vasopressors but the concomitant administration of dobutamine helps maintain O_2ER.

In contrast to other vasopressors, lactate concentrations frequently rise during epinephrine therapy resulting in variable arterial pH values. The increase in lactate may be a result of worsened DO_2 to the liver (and subsequent anaerobic metabolism) or to the hepatosplanchnic circulation, a direct increase in calorigenesis, and breakdown of glycogen (enhanced aerobic lactate production via β_2-adrenergic receptor stimulation), or lactate mobilization. Of all the vasopressors, epinephrine exhibits the most pronounced capacity to induce hyperglycemia by increased gluconeogenesis and glycogenolysis with α-mediated suppression of insulin secretion.

Phenylephrine

Phenylephrine is essentially a pure α_1-agonist and increases blood pressure primarily through vasoconstriction.[26–28,82] Given the presence of cardiac α_1-receptors, phenylephrine also may increase contractility and CO, although variable effects on CO are observed. It is a therapeutic option in hypotensive patients experiencing a tachyarrhythmia when a vasopressor with minimal to no β_1-agonist activity is indicated.[27,28]

Phenylephrine is a selective α_1-agonist with primarily vascular effects.[26–28,82] As with other vasopressors, phenylephrine dosages required to achieve goals of therapy are significantly higher than dosages traditionally recommended for use. Phenylephrine 0.5 to 9 µg/kg/min, used alone or in combination with dobutamine or low dosages of dopamine, improves blood pressure and myocardial performance in fluid-resuscitated patients with vasodilatory/distributive shock. Incremental doses of phenylephrine result in linear dose-related increases in SVR and MAP when administered alone in stable, normotensive but hyperdynamic, volume-resuscitated surgical ICU patients. In septic shock, phenylephrine does not significantly impair the cardiac index, PAOP, or peripheral perfusion. Phenylephrine improves MAP by increasing SVR and stroke index through an enhanced venous return to the heart.

In septic shock, phenylephrine increases global tissue oxygen use, although data regarding the relationship of the oxygen-transport variables with increases in MAP and cardiac index are conflicting. Increases in VO_2 are dissociated from DO_2, representing an increase in O_2ER, as the cardiac index remains unchanged. Increases in VO_2 may result from redistribution of blood flow to previously under perfused areas, improving oxygen use because of changes in MAP and SVR. Evidence of globally improved peripheral tissue perfusion is observed as lactic acid concentration declines or remains unchanged and urine production increases significantly at increased or maximal VO_2. An increased O_2ER may contribute to improved tissue response.

Few data regarding the effect of phenylephrine on regional hemodynamics and oxygen transport variables are available. When phenylephrine replaced norepinephrine in patients with septic shock, phenylephrine selectively reduced splanchnic blood flow, DO_2, and lactate uptake rate without changing the overall splanchnic VO_2. Concomitantly, arterial lactate concentrations increased. Because all these parameters normalized when norepinephrine was reinstated, these data suggest that exogenous β-adrenergic stimulation (with norepinephrine) may determine hepatosplanchnic perfusion and oxygen availability but not utilization in septic shock. Phenylephrine and norepinephrine demonstrate similar short-term hemodynamic profiles and indices of global and regional perfusion when used as an initial vasopressor in septic shock.[26–28]

Dopamine

Dopamine has been described as having dose-related receptor activity at D_1-, D_2-, β_1-, and α_1-receptors.[26–29,80] This dose-response relationship has not been confirmed in critically ill patients. In patients with shock, a significant overlap of hemodynamic effects occurs, even at dosages as low as 3 µg/kg/min. Historically, dopamine was frequently utilized but is no longer considered a first-line therapy for shock.[20,27]

Dopamine is a natural precursor to norepinephrine and epinephrine and is generally not as effective as these two agents for achieving goal MAP in patients with shock.[26–28,80] Most studies of patients with septic shock have shown that dopamine at dosages of 5 to 10 µg/kg/min increases CO by improving contractility and heart rate, primarily from its β_1 effects. At higher dosages (>10 µg/kg/min), it increases MAP because of both increased CO and SVR due to its combined β_1 and α_1 effects.

The clinical utility of dopamine as a vasopressor in the setting of shock is limited because large dosages are frequently necessary to maintain CO and MAP. At dosages exceeding 20 µg/kg/min, further improvement in cardiac performance and regional hemodynamics is limited. The effect of dopamine on global oxygen-transport variables parallels the hemodynamic effects. Although dopamine improves global DO_2, it may compromise O_2ER in the splanchnic and mesenteric circulations by α_1-mediated vasoconstriction. Splanchnic blood flow and DO_2 increase with dopamine, but with no preferential increase in splanchnic perfusion as a fraction of CO and systemic increases in DO_2. Large doses of dopamine cause a decrease or lack of change in regional VO_2 and a decrease in tissue O_2ER. Dopamine at low or vasopressor dosages directly impedes gastric motility in critical illness and may aggravate gut ischemia in shock. Similar to high-dose administration, low-dose dopamine increases splanchnic blood flow but lowers splanchnic VO_2 in sepsis. Therefore, dopamine at all dosages impairs hepatosplanchnic metabolism despite an increase in regional perfusion. Low dosages (eg, 2 µg/kg/min) increase renal blood flow and glomerular filtration rate in studies of animals and healthy volunteers, but urine production is similar to placebo in critically ill patients.[87]

Dobutamine

Dobutamine, a synthetic catecholamine, is primarily a selective β_1-agonist with mild β_2- and α_1-activity, resulting in strong positive inotropic activity without concomitant vasoconstriction.[26–28] In comparison with dopamine, dobutamine produces a larger increase in CO and is less arrhythmogenic. α_1-Adrenoceptors in the heart are directly stimulated by the (−) isomer of dobutamine, but β_1 and β_2 activity reside in the (+) isomer. The strong inotropic action of dobutamine is a function of its structure, the additive effect of cardiac α_1- and β_1-agonist activity, and a relatively weak chronotropic effect limited to the (+) isomer action on the β-receptors. Clinically, β_2-induced vasodilation and increased myocardial contractility with subsequent reflex reduction in sympathetic tone lead to a decrease in SVR. Optimal uses of dobutamine in shock are for patients with low CO and high filling pressures (eg, left ventricular dysfunction demonstrated with echocardiography) or ongoing signs of global or regional hypoperfusion despite adequate resuscitation; however, vasopressors may be needed to counteract arterial vasodilation.[20,27]

Dobutamine is an inotrope with vasodilatory properties (an “inodilator”).[26–28] It is used for the treatment of septic and cardiogenic shock to increase the CO, typically by 25% to 50%. In septic shock, left and right ventricular functions are depressed despite a high CO, whereas ventricular volumes and compliance are increased. Dobutamine increases stroke volume, left ventricular stroke work index, and thus cardiac index and DO_2 without increasing PAOP.[26–28] It also enhances the chronotropic effect. The combination of dobutamine and norepinephrine results in a lower increase in heart rate compared with the use of epinephrine alone.

Dobutamine increases DO_2 without affecting VO_2, resulting in decreased O_2ER. Arterial lactate concentrations decrease significantly with norepinephrine and dobutamine compared with dopamine and epinephrine infusions. The addition of dobutamine to other vasopressors improves gastric mucosal perfusion even without increases in CO. This effect may relate to blood flow redistribution toward gastric mucosa. Dobutamine may increase the fraction of CO distributed to the global hepatosplanchnic blood flow. Additionally, dobutamine may redistribute blood flow within gastric wall layers toward the mucosa by “stealing” blood from the muscularis secondary to greater β_2-mediated vasodilation. Sublingual microcirculation improves after dobutamine is added to vasopressor-dependent septic shock patients in a manner unrelated to arterial pressure or CO, suggesting that enhanced perfusion is the result of the “steal” phenomenon. Of note, gastric mucosal perfusion and tissue oxygen utilization are most improved with concurrent norepinephrine and dobutamine therapies compared with other vasopressor combinations at the same level of MAP.

Vasopressin

Initiating vasopressin in patients with vasodilatory/distributive shock increases SVR and arterial blood pressure, which allows for reductions in the dosage requirements of catecholamine adrenergic agents.[29,31,82,88–91] Vasopressin's strongest vasoconstrictive action occurs in the skin and soft tissues, skeletal muscles, and fat tissues.[29] Vasopressin decreases heart rate after initiation because of reflex bradycardia from increased SVR.[92] Unlike adrenergic receptor agonists, the vasoconstrictive effects of vasopressin are preserved during hypoxemia, and pulmonary arterial pressures do not increase with vasopressin. After initiation of vasopressin, organ-specific vasodilation may preserve cardiac and renal function. Whereas V_2 stimulation promotes water retention from the distal tubules and collecting ducts, V_1-receptors cause vasoconstriction of efferent renal arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate, enhancing urine production.[29,93]

Because vasopressin increases SVR through vasoconstriction, it may be utilized as a component of therapy for patients with vasodilatory/distributive shock. Studies involving vasopressin infusion for management of septic shock show rapid and sustained improvement in blood pressure.[29,88–90] These effects are evident with the administration of dosages up to 0.04 units/min. Administration of dosages >0.04 units/min may be associated with negative changes in CO and mesenteric mucosal perfusion; however, these results are inconsistent in studies.[29,33] Cardiac ischemia and reductions in stroke volume are rare when dosages of 0.04 units/min or lower are used.[33] However, higher dosages of vasopressin in patients with septic shock complicated by impaired left ventricular systolic function warrant extreme caution. Although vasopressin may have deleterious effects on mesenteric and skin perfusion, studies report vasodilation of cerebral, pulmonary, coronary, and some renal vasculature beds. The clinical outcomes associated with selective vasodilation are not yet known except for the possibility of enhanced urine production in patients not anuric at baseline.[93]

Angiotensin II

Angiotensin II increases SVR and may be utilized for patients with vasodilatory/distributive shock. Blood pressure rapidly increases after initiation of angiotensin II in patients with low SVR (ie, those with vasodilatory/distributive shock). The starting dosage of angiotensin II is 10 to 20 ng/kg/min with rapid titration (as quickly as every 5 minutes) to MAP goal. In the first 3 hours of treatment, the dosage may be increased up to 80 ng/kg/min; thereafter, the dosage should not exceed 40 ng/kg/min. The effects of angiotensin II on myocardial performance, oxygen transport parameters, and regional organ perfusion are unclear. However, because the risk of lactic acidosis and delirium are higher with angiotensin II, there may be a deleterious effect on regional tissue perfusion.[33,91] Angiotensin II has only been evaluated in patients without depressed CO; therefore, it should also be used with extreme caution in patients with impaired left ventricular systolic function. Angiotensin II also increases glomerular perfusion pressure and filtration, but its effects on kidney function are unclear.[33] Angiotensin II increases heart rate through unclear mechanisms, but likely due to activation of AT-1 receptors in the heart.[32,33]

Comparative Studies of Vasoactive Agents

The results of several observational and randomized studies support norepinephrine as the first-line vasopressor for most shock states, particularly septic shock.[20,27] A meta-analysis showed that norepinephrine was associated with increased survival compared to dopamine.[82] Tachydysrhythmias were less common with norepinephrine. The results of one study contributed to the majority of data. The study randomized patients with shock unresponsive to volume resuscitation to norepinephrine or dopamine and found similar 28-day mortality rates.[4] Despite the theoretical advantages of dopamine in patients with cardiogenic shock, dopamine was not superior to norepinephrine in patients with this shock type. Overall, patients receiving norepinephrine had fewer arrhythmic events and more vasopressor-free days. This study demonstrates that while there is no mortality benefit of norepinephrine over dopamine in heterogeneous shock syndromes, it is more effective in increasing blood pressure and is safer.

Two randomized, double-blind studies compared epinephrine with norepinephrine in patients with shock.[86,94] Both studies found similar 28-day mortality rates and time to vasopressor withdrawal with epinephrine and norepinephrine. One study found more events of tachyarrhythmias with epinephrine leading to study discontinuation.[86] Both studies also showed that epinephrine was associated with lower arterial pH values and higher serum lactate concentrations over the first days of therapy. Another study compared norepinephrine and epinephrine in patients with cardiogenic shock after acute myocardial infarction.[95] Cardiac index was higher with epinephrine over the first 4 hours of treatment, but there was no difference between groups over the 72-hour study period. The study was stopped early because of a higher incidence of refractory cardiogenic shock in patients receiving epinephrine. Survival was similar between study groups, but the study was not designed or statistically powered to evaluate this outcome. These data suggest that norepinephrine is preferred to epinephrine in patients with cardiogenic shock.

Taken together, norepinephrine is the primary vasopressor of choice in patients in most shock states because of its multiple benefits: (1) norepinephrine may decrease mortality in septic shock; (2) it reverses inappropriate vasodilation and low global oxygen extraction; (3) it attenuates myocardial depression at unchanged or increased CO and increased coronary blood flow; (4) it improves renal perfusion pressure and renal filtration; (5) it enhances splanchnic perfusion; and (6) it is less likely than many other vasopressors to cause tachydysrhythmias.[26–28,80]

Two meta-analyses concluded that adjunctive vasopressin did not produce a survival benefit in patients with vasodilatory/distributive shock,[88,96] while a third meta-analysis showed vasopressin reduced mortality.[89] Furthermore, a meta-analysis utilizing patient-level data of patients with septic shock did not detect a survival benefit with vasopressin.[97] The largest meta-analysis and the individual patient data meta-analysis showed the addition of vasopressin to catecholamine vasopressors was associated with a lower risk for atrial fibrillation and arrhythmias overall.[96,97] The results of one study contributed the majority of data for all meta-analyses. This study randomized patients with septic shock to vasopressin 0.01 to 0.03 units/min or norepinephrine, added to open-label catecholamine therapy, and 28-day mortality rates were similar.[90] Subgroup analyses suggested a mortality benefit with vasopressin in patients with less severe shock. The adverse event profiles were similar between groups and vasopressin therapy expedited the discontinuation of catecholamine vasopressors. Although vasopressin helped preserve renal function in patients with acutely declining urine production,[93] a subsequent randomized study of early vasopressin in patients with septic shock did not detect a difference between norepinephrine and vasopressin in the number of kidney failure-free days.[98] At present, vasopressin should not be used for the sole purpose of improving or maintaining renal function.

A study compared norepinephrine and vasopressin in patients with vasodilatory/distributive shock after cardiac surgery.[99] The incidence of a composite outcome of mortality or severe complications (stroke, requirement for mechanical ventilation for longer than 48 hours, deep sternal wound infection, reoperation, or acute kidney injury) was lower in patients receiving vasopressin. There was a lower incidence of acute kidney injury in patients receiving vasopressin but no difference between groups in mortality or other components of the composite outcome. Vasopressin may be considered as a component of vasopressor therapy for patients with vasodilatory/distributive shock after cardiac surgery.

Few studies to date have evaluated angiotensin II as a therapy for shock. In one study, patients with vasodilatory shock (81% septic shock) requiring a norepinephrine dosage of at least 0.2 μg/kg/min without evidence of a low CO were randomized to angiotensin II or placebo.[91] Compared with those receiving placebo, patients receiving angiotensin II more frequently achieved an MAP of at least 75 mm Hg (higher than recommended by guidelines) without an increase in the dosage of open-label vasopressors after 3 hours. Angiotensin II was also associated with lower open-label vasopressor doses over 3 hours. There was no difference between groups in organ function after 48 hours or mortality at day 28. Although a secondary analysis of the study suggested a mortality benefit with angiotensin II in patients with acute kidney injury treated with renal replacement therapy at study enrollment,[100] angiotensin II should not be started exclusively for this indication.

Several randomized controlled trials of low-dose corticosteroids in vasopressor-dependent septic shock patients have been published.[101,102] The results of meta-analyses are conflicting with regard to a survival benefit associated with corticosteroid administration; however, they are in agreement that corticosteroid use improves hemodynamics with more rapid shock reversal and shorter durations of vasopressor support.[101,102] Studies that showed a mortality benefit included ill patients requiring high-dose vasopressors (average norepinephrine dosages about 1 μg/kg/min); studies that did not detect a mortality benefit enrolled patients who were not as sick (average norepinephrine dosages 0.5 μg/kg/min or below). Discrepancies in study designs and conflicting results have led to an ongoing debate about the optimal use of corticosteroids in patients with septic shock.

TABLE e42-5

Receptor Pharmacology and Adverse Events of Selected Vasopressor and Inotropic Agents Used in Shock[a]

Agent (Adverse Events)	α_1	α_2	β_1	β_2	D	V_1	V_2	AT-1	AT-2
Angiotensin II (5,000-10,000 ng/mL NS)	Tachycardia, thrombosis, peripheral ischemia, lactic acidosis, bronchospasm, infection								
1.25-80 ng/kg/min	0	0	0	0	0	0	0	++++	++++

Dobutamine (500-4,000 µg/mL D_5W or NS)	Tachycardia, dysrhythmias, hypotension								
2-10 µg/kg/min	+	0	++++	++	0	0	0	0	0
>10-20 µg/kg/min	++	0	++++	+++	0	0	0	0	0
Dopamine (800-3,200 µg/mL D_5W or NS)	Tachycardia, dysrhythmias, decreased PaO_2, mesenteric hypoperfusion, GI motility inhibition, T-cell inhibition								
1-3 µg/kg/min	0	0	+	0	++++	0	0	0	0
3-10 µg/kg/min	0/+	0	++++	+	++++	0	0	0	0
>10-20 µg/kg/min	+++	0	++++	+	0	0	0	0	0
Epinephrine (8-16 µg/mL D_5W or NS)	Tachycardia, dysrhythmias, mesenteric hypoperfusion, increased lactate, hyperglycemia, immunomodulation								
0.01-0.05 µg/kg/min	++	++	++++	+++	0	0	0	0	0
0.05-3 µg/kg/min	++++	++++	+++	+	0	0	0	0	0
Norepinephrine (16-64 µg/mL D_5W or NS)	Mixed effects on myocardial performance and mesenteric perfusion, peripheral ischemia, immunomodulation								
0.02-3 µg/kg/min	++++	+++	+++	+/++	0	0	0	0	0
Phenylephrine (100-400 µg/mL D_5W or NS)	Mixed effects on myocardial performance, peripheral ischemia								
0.5-9 µg/kg/min	+++	+	+	0	0	0	0	0	0
Vasopressin (0.2-1 units/mL D_5W or NS)	Mixed effects on myocardial performance, mesenteric hypoperfusion, peripheral ischemia, thrombocytopenia, hyperbilirubinemia								
0.01-0.1 units/min	0	0	0	0	0	++++	++++	0	0

AT, angiotensin; D, dopamine; D_5W, dextrose 5% in water; GI, gastrointestinal; NS, normal saline (0.9% sodium chloride); PaO_2, arterial oxygen pressure; V, vasopressin.

[a] Activity ranges from no activity (0) to maximal (++++) activity.

Use of Vasopressors and Inotropes in Distributive (Septic) Shock

The Surviving Sepsis Campaign guidelines outline vasopressor and inotrope selection, and corticosteroid use for patients with septic shock.[20] Other evidence relative to vasopressor and inotrope choice is available from systematic reviews and meta-analyses.[80,82,88,89,96,103,104] Guidelines from the Society of Critical Care Medicine and European Society of Intensive Care Medicine also outline corticosteroid use in patients with septic shock,[36] and systematic reviews and meta-analyses also exist on the topic.[101,102] ⑩ Overall, the recommendations from all of these sources support norepinephrine as the first-line vasopressor for shock.

In patients with vasodilatory/distributive shock, norepinephrine should be started when an MAP ≥65 mm Hg and/or adequate tissue perfusion is not achieved with fluid resuscitation. Norepinephrine infusions are initiated at 0.05 to 0.1 μg/kg/min and rapidly titrated to preset blood pressure goals (usually MAP ≥65 mm Hg) and/or improvement in global and regional peripheral perfusion (eg, decrease blood lactate or restore urine production). Norepinephrine may be associated with tachydysrhythmias, with higher doses more likely to cause this adverse drug reaction.

Epinephrine is considered as adjunctive therapy to norepinephrine because it is associated with tachydysrhythmias and lactate elevation.[26–28,82,86] Epinephrine-associated clinically important dysrhythmias or cardiac ischemia occur at variable rates irrespective of age or underlying cardiac status.[26–28,82,86] Nevertheless, caution must be exercised before considering epinephrine for managing hypoperfusion in patients with coronary artery disease and inadequate CO, in whom ischemia, chest pain, or myocardial infarction may result. Epinephrine is commonly used in countries where other agents may not be readily available or are relatively expensive. It may also be used as an inotrope after cardiac surgery, particularly in patients with revascularized coronary circulation.

Despite its use in refractory shock, little information is available regarding the clinical efficacy of phenylephrine. It improves myocardial performance in hyperdynamic, normotensive patients with sepsis but worsens myocardial performance in patients with cardiogenic shock as a result of a decrease in CO and an increase in SVR. Therefore, phenylephrine use warrants caution and should not be used as an initial vasopressor in shock patients with impaired myocardial performance. The available data on hemodynamics, oxygen-transport variables, and mortality with phenylephrine in shock patients may not be generalizable because of the small numbers of patients evaluated. Tachydysrhythmias are notably infrequent with phenylephrine, particularly when it is used as a single agent or at higher doses, because phenylephrine exerts little activity on β_1-adrenergic receptors. Whether the beneficial effects can be sustained with longer administrations of phenylephrine is unclear. Phenylephrine may be a useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmias with use of norepinephrine or epinephrine.[82]

The use of dopamine as a first-line vasopressor is no longer recommended. Its clinical use is frequently hampered by tachycardia and tachyarrhythmias, which may lead to myocardial ischemia.[4] Although tachyarrhythmias theoretically should not be expected to occur until the administration of dopamine 5 to 10 μg/kg/min, β_1 effects are observed with dosages as low as 3 μg/kg/min. While dopamine may improve hemodynamic function, the use of dopamine for shock is questionable because regional hemodynamics, oxygen-transport variables, and functional parameters of improved organ perfusion are not consistently enhanced in a sustained manner and may be negatively impacted.[6] Low-dose dopamine did not demonstrate improved renal function in a randomized, placebo-controlled study of critically ill patients with early renal dysfunction.[87] A meta-analysis confirmed that low-dose dopamine fails to enhance renal function or survival in critically ill patients.[105] The negative findings of low-dose dopamine use and the deleterious effects of inotropic and vasopressor dosages of dopamine on regional hemodynamics, oxygen transport, and functional performance of organ perfusion raise concern over whether dopamine should even be considered in patients with shock.[20,87,105]

Current guidelines for patients with septic shock recommend a trial of dobutamine infusion, titrated up to 20 μg/kg/min, in the presence of myocardial dysfunction (elevated cardiac filling pressures, low CO, echocardiography displaying left ventricular dysfunction) or continued signs of global or regional hypoperfusion despite meeting volume and MAP goals.[20] Increased cardiac performance measures in response to adjunctive dobutamine therapy are predictive of survival during sepsis. However, administration of dobutamine purely to achieve a normal CO, DO_2, or $S\text{cv}O_2$ in the absence of other signs of tissue hypoperfusion (eg, low urine production) is not recommended. The achievement of supranormal oxygen transport values with dobutamine is of little value compared with treatment to normal values. In addition, administration of dobutamine to achieve these high values may increase mortality rate and/or the incidence of adverse drug reactions.

Dobutamine should be started at dosages ranging from 2.5 to 5 μg/kg/min. Dosage increments of dobutamine beyond 20 μg/kg/min are limited by tachycardia, myocardial ischemia, hypertension, and tachyarrhythmias despite the absence of preexisting cardiac abnormalities. Although a dose-response may be seen, dosages >5 μg/kg/min may provide limited beneficial effects on oxygen transport values and hemodynamics and may increase adverse cardiac effects. If given to patients who have an inadequate venous return, dobutamine will result in hypotension and a reflexive tachycardia. Because dobutamine increases myocardial oxygen demand, it should be used cautiously in patients with cardiogenic shock, particularly those with acute myocardial infarction who have not undergone coronary revascularization.[11] Doses should be guided by clinical endpoints, echocardiography, and global perfusion goals. Dobutamine, like other inotropes, is usually given until improvement in myocardial function occurs or dose-limiting adverse drug reactions are observed.

Additional vasoactive agents (eg, vasopressin and/or angiotensin II and/or corticosteroids) may be added to improve MAP or decrease catecholamine requirements. However, specific catecholamine dosage thresholds indicating the initiation of these adjunctive agents are unclear.

Adjunctive use of vasopressin to prevent dose escalation of adrenergic agents, decrease norepinephrine dosage, or increase MAP should be considered in patients with vasodilatory/distributive shock. A meta-regression showed a negative correlation between vasopressin and norepinephrine dosages.[88] Small studies of septic shock patients demonstrate that initial therapy with vasopressin achieves blood pressure control as effectively as traditional catecholamine vasopressors but the response is delayed.[29] Therefore, vasopressin therapy should be used as add-on therapy to catecholamine adrenergic agents rather than as first-line therapy.[20,29] In patients with septic shock, dosages are generally fixed at 0.03 or 0.04 units/min with higher doses reserved for salvage therapy (norepinephrine dosage >0.6 μg/kg/min).[20] The results of studies showed that vasopressin markedly reduced the requirements for adrenergic agents.[29,88–90] Therefore, vasopressin should be used when the response to initial adrenergic therapy is inadequate or as a method for reducing the dosage of these therapies.[20] Increased arterial pressure should be evident within the first hour of vasopressin therapy, at which time the dose(s) of adrenergic agent(s) should be reduced while maintaining goal MAP. In patients with vasodilatory shock after cardiac surgery, vasopressin is frequently titrated to the MAP goal with dosages up to 0.1 units/min.[99]

Mesenteric ischemia associated with vasopressin may be clinically relevant. Increased hepatic transaminases and total bilirubin concentrations may occur with vasopressin therapy, suggesting impaired hepatic blood flow or a direct effect on excretory hepatic function.[29,33] While mesenteric vasoconstriction occurs at low vasopressin serum concentrations, studies indicate that only vasopressin dosages exceeding 0.04 units/min worsen gastric mucosal perfusion when it is added to low or high dosages of catecholamine vasopressors.[29] The effect is additive with norepinephrine despite substantially reduced dosages of norepinephrine when vasopressin is initiated. Ischemic skin lesions have also been observed in several studies, with an occurrence rate as high as 30% after vasopressin was added to norepinephrine-resistant shock.[29] Digital ischemia is also significantly more frequent with vasopressin (2% higher absolute risk increase).[96,97] However, meta-analyses concluded that there was no difference in overall serious adverse events between vasopressin and control.[88,89,96,97]

Several studies reported difficulty discontinuing vasopressin therapy. Because vasopressin is often used to replace a physiologic deficiency in patients with septic shock, it stands to reason that the requirement for vasopressin will subside with reversal of the underlying septic process. Whether vasopressin should be stopped prior to or after catecholamine vasopressors is unclear.[33] Long-term administration of vasopressin may be associated with hyponatremia and thrombocytopenia.

The optimal use of angiotensin II is unclear although it is most frequently used as adjunctive therapy to norepinephrine and vasopressin in the treatment of patients with vasodilatory/distributive shock.[106] However, angiotensin II is associated with a number of adverse drug reactions due to its action on angiotensin receptors throughout the body. It increases the risk of thromboembolic events, particularly deep vein thrombosis. This adverse drug reaction is likely due to the release of plasminogen activator inhibitor-1 (resulting in inhibition of fibrinolysis) and platelet activation.[31,33] Because of this risk, concurrent thromboembolism prophylaxis should be utilized. Heart rate significantly increases after angiotensin II initiation, and this agent should be used cautiously in those who cannot tolerate an increase in heart rate (eg, older patients with coronary artery disease). Through unclear mechanisms, patients receiving angiotensin II have a higher risk for secondary infection, particularly fungal infection.[33,91] Angiotensin II has been associated with bronchospasm and should be avoided in patients with asthma or current bronchospasm.[31,33]

Treatment of septic shock with corticosteroids improves hemodynamic variables and lowers catecholamine vasopressor dosages with minimal effects on patient safety.[20,36] Corticosteroids should be considered when fluids and vasopressors are unable to restore hemodynamic stability, or when weaning of vasopressor therapy proves futile.[36,101,102] They should also be started in cases of shock when adrenal insufficiency is suspected (eg, patients receiving long-term corticosteroid therapy for other indications prior to the onset of shock); however, assessment of adrenal function to guide therapy is not recommended.[20,36] Adverse events with corticosteroids for shock are few because corticosteroids are administered for a finite period of time, usually 7 days. Studies suggest that short-term, low-dose corticosteroids do not alter the rates of gastrointestinal bleeding and superinfections, but increase the risk for hypernatremia and hyperglycemia, and may increase the risk of neuromuscular weakness.[101,102] Acutely elevated serum concentrations of blood urea nitrogen and white blood cell count may also occur. The reader is referred to Chapter 142 "Sepsis and Septic Shock" for further discussion of this topic.

Use of Vasopressors and Inotropes in Hypovolemic (Hemorrhagic/Traumatic) Shock

Guidelines specific to the management of major bleeding and coagulopathy after trauma also outline vasopressor and inotrope use.[39] In contrast to other forms of shock such as vasodilatory/distributive, medications are a distant alternative to the primary therapy for hypovolemic shock, fluids. In hypovolemic shock, peripheral resistance is high due to compensatory mechanisms aimed at maintaining tissue perfusion. Early or overzealous use of vasopressors in lieu of fluids may exacerbate this resistance to the point that flow is stopped. Vasopressors are only used as a temporizing measure or as a last resort when all other measures to maintain perfusion have been exhausted.[27] Because vasopressors have such a limited role in hypovolemic shock, few studies compare various agents. However, norepinephrine is considered the first-line vasopressor of choice.

Integrated Use of Fluids, Vasopressors, and Inotropes in Shock Therapy

The initial goals of therapy are to restore effective tissue and organ perfusion. Priority should be placed on the ABCs of life support (ie, airway, breathing, and circulation), assessment of vital signs and mental status, and determination of tissue perfusion (eg, urine production after catheterization). The underlying cause of the patient's tissue hypoperfusion should be evaluated because this leads to the correct treatment approach. For example, in hemorrhagic shock due to trauma, the most important intervention is surgical control of bleeding, and anything that delays this control is likely to increase, not decrease, mortality. If patients have signs of tissue hypoperfusion and their clinical syndrome is consistent with a shock state that is fluid responsive (eg, hypovolemic), an initial fluid challenge of at least 500 mL of crystalloid fluid should be administered.

Current recommendations for patients with sepsis are to measure blood lactate concentration (and remeasure if initial lactate is >2 mmol/L), begin rapid administration of 30 mL/kg crystalloid for hypotension, and obtain MAP ≥65 with vasopressors if patient is hypotensive during or after fluid resuscitation, all started within 1 hour of recognition.[20] Although protocolized initial treatment of patients with septic shock is not better than usual care, usual care must include rapid (ie, within 1 hour of recognition) antibiotic administration and aggressive fluid resuscitation.[20] Figure e42-5 presents an algorithm for the management of patients with shock.[1,2,20,25–28,39] This algorithm suggests a stepwise approach to optimize MAP, first with crystalloid fluid resuscitation then adding norepinephrine. Although albumin is not recommended for the prevention or initial treatment of circulatory insufficiency, its use may be appropriate in patients who are not responding to crystalloids and are developing problems such as interstitial fluid accumulation. Patients with evidence of inadequate CO without fluid responsiveness should have an inotrope initiated or mechanical circulatory support considered. Inotropes may be added for shock states with low CO or left ventricular dysfunction. Occasionally, epinephrine and phenylephrine are used when necessary. Although this approach is empirical, it is used broadly in clinical practice and has been justified by the desire to avoid the adverse events associated with strong vasoconstriction.

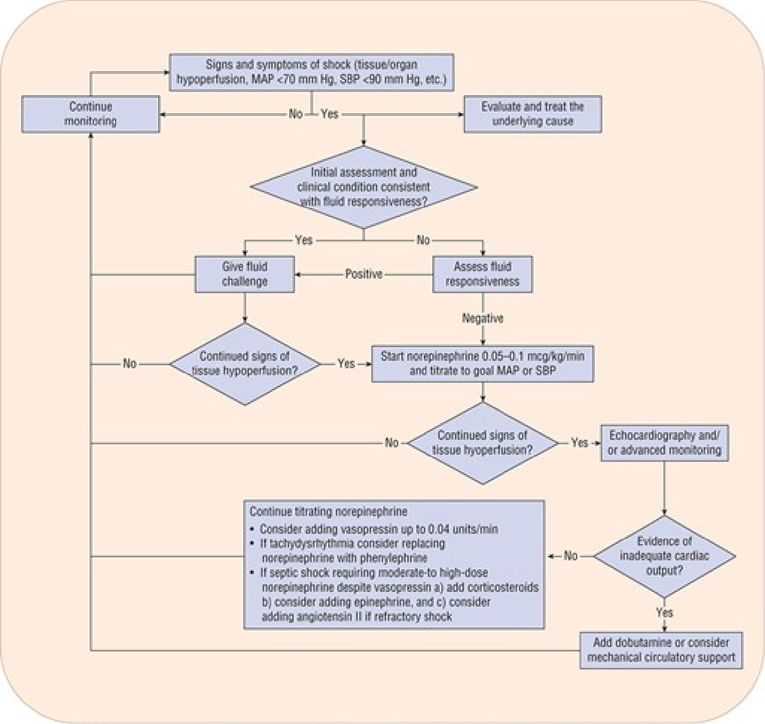
Developing a strategy to rapidly restore effective tissue perfusion reduces mortality. Goals of initial resuscitation should include crystalloid fluids if the patient is fluid responsive, vasopressor agents to achieve MAP at least 65 mm Hg (or SBP 80-90 mm Hg in trauma patients), and frequent clinical assessments to meet global and regional perfusion goals (eg, additional fluid challenge or inotropic therapy to achieve lactate clearance ≥20%, capillary refill time <3 seconds, $ScvO_2$ ≥70% [0.70] or urine production ≥0.5 mL/kg/hr).[1,20] Patients who develop supranormal DO_2 and VO_2 values have lower mortality, but targeting these with exogenous administration of vasopressors/inotropes is not beneficial and cannot be recommended.

Vasopressors should be initiated if tissue perfusion is not responding to fluid challenges. Dosage titration and monitoring of vasopressor and inotropic therapy should be guided by the "best clinical response", lactate clearance, and capillary refill time.[1,2,20,26–28,39] Clinically effective dosing of vasopressors and inotropes in shock often requires dosages much higher than recommended by most references.[1,2,20,26–28,39] These large doses must be tempered with the development of adverse drug reactions. The goal is to use the lowest effective dosage while minimizing evidence of global hypoperfusion (lactate, $ScvO_2$, capillary refill time) and regional hypoperfusion such as myocardial (eg, tachyarrhythmias, electrocardiographic changes, troponin elevations), renal (decreased glomerular filtration rate and/or urine production), splanchnic/gastric (bowel ischemia, elevated transaminases), pulmonary (worsening PaO_2), or peripheral (capillary refill time, cold extremities) ischemia. Therapy with catecholamine vasopressors and inotropes is continued until myocardial depression and/or vascular hyporesponsiveness (ie, blood pressure) of shock improve, usually measured in hours to days.[20,27]

This algorithmic approach (Fig. e42-5) is consistent with the recommendations made in the Surviving Sepsis Campaign guidelines and other guidance for the monitoring and treatment of patients with shock.[1,2,14,20,25–28,39] Personalized pharmacotherapy for hemodynamic support of shock may be rational in certain situations (such as long-standing baseline hypertension, or home corticosteroid use) but may be difficult to achieve because the patient response is variable and the acute nature of emergent resuscitation often necessitates treatment before pharmacotherapy can be personalized. Effectiveness and safety may be influenced by genetic polymorphisms; therefore, future vasopressor therapies may be directed based on pharmacogenomic profiles.

FIGURE e42-5

Treatment algorithm for shock syndromes.



Signs and symptoms of shock (tissue/organ hypoperfusion, MAP <70 mm Hg, SBP <90 mm Hg, etc.)
Continue monitoring
No
Yes
Evaluate and treat the underlying cause
Initial assessment and clinical condition consistent with fluid responsiveness?
Yes
No
Give fluid challenge
Positive
Assess fluid responsiveness
Negative
No
Continued signs of tissue hypoperfusion?
Yes
Start norepinephrine 0.05–0.1 mcg/kg/min and titrate to goal MAP or SBP
No
Continued signs of tissue hypoperfusion?
Yes
Echocardiography and/ or advanced monitoring
Continue titrating norepinephrine
• Consider adding vasopressin up to 0.04 units/min
• If tachydysrhythmia consider replacing norepinephrine with phenylephrine
• If septic shock requiring moderate-to high-dose norepinephrine despite vasopressin a) add corticosteroids b) consider adding epinephrine, and c) consider adding angiotensin II if refractory shock
No
Evidence of inadequate cardiac output?
Yes
Add dobutamine or consider mechanical circulatory support

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be frequently monitored for their response to therapy. If perfusion is not restored with the initial treatment approach, then echocardiography should be pursued with additional treatment options implemented based on the findings. Additional hemodynamic monitoring with a pulmonary artery catheter should be considered in complex patients (eg, those with mixed shock states) or when a clinician is questioning the validity of perfusion assessments or measurements from other monitoring devices. The pulmonary artery catheter (ie, a Swan-Ganz catheter) provides multiple cardiovascular parameters, including CVP, pulmonary artery pressure, PAOP (commonly called the "wedge pressure"), CO, SVR, and SvO_2. However, because the pulmonary artery catheter is more invasive (leading to a higher risk of complications) than a central venous catheter and not associated with improved clinical outcomes, it should not be used routinely for patients with shock.[1,107] Semi-invasive and minimally invasive hemodynamic monitoring devices are increasingly utilized in patients with shock but are beyond the scope of this chapter.[108]

Several laboratory tests are indicated for monitoring of shock in the ICU setting. These include assays for assessing possible electrolyte alterations and kidney perfusion (eg, blood urea nitrogen and creatinine). Among other things, a complete blood count will enable assessment of possible infection (white blood cell count), the oxygen-carrying capacity of the blood (hemoglobin, hematocrit), and ongoing bleeding (hemoglobin, hematocrit), and hemostasis potential (platelet count). In bleeding patients, clotting factors are lost and diluted; therefore, concomitant monitoring of coagulation function through laboratory tests (eg, PT/INR and platelets) or viscoelastic tests (eg, thromboelastography) with corresponding measures of support should be initiated.[39] Increasing blood lactate concentration, increasing arterial base deficit, or decreasing bicarbonate concentration are global markers indicative of inadequate perfusion leading to anaerobic metabolism. The value of these surrogate markers for improving patient outcomes is controversial, but they are considered traditional endpoints of resuscitation, particularly for trauma patients. Other tests may be indicated if organ dysfunction is likely. For example, when blood flow to the liver is interrupted because of sustained hypotension, a condition known as shock liver may occur. In this condition, the levels of transaminases on a liver panel may be markedly elevated in the first couple of days after marked hypotension, although the concentrations should decrease over time. Along with laboratory testing, a more extensive history can be obtained during the subacute monitoring period.

In patients responding to initial therapy, discontinuation of vasopressor or inotropic therapy should be executed slowly; therapy should be “weaned” to avoid a precipitous worsening in regional and systemic hemodynamics. Careful monitoring of global and regional endpoints also should be geared toward discontinuation of vasopressors and inotropes as soon as the patient is hemodynamically stable. This requires constant observation. Because vasopressors and inotropes often are started while the patient is not yet optimally volume resuscitated, clinicians should reevaluate fluid responsiveness frequently so that the patient can be weaned from the vasopressor as soon as possible. Dosages should be titrated downward approximately every 10 minutes to determine if the patient can tolerate gradual withdrawal and eventual discontinuation of the vasopressor and/or inotrope. Discontinuation of agents may occur only minutes to hours after their initiation, or it may take days to weeks. Shock requiring vasopressor and/or inotropic support usually resolves within several days to 1 week.

CONCLUSION

The presence of circulatory shock is indicated by inadequate global tissue perfusion. Shock syndromes are typically classified into hypovolemic, cardiogenic, obstructive, or vasodilatory/distributive shock. Differentiation of these syndromes is conceptually based on the evaluation of preload, cardiac output, and afterload. Patients require close monitoring, including assessment of organ and tissue perfusion, adequate DO_2, and fluid responsiveness.

Crystalloids and norepinephrine are the recommended first-line fluid and vasopressor, respectively, for shock.[2,20,27,39] Balanced salt solutions may be preferred to 0.9% sodium chloride as the initial crystalloid solution. The choice of additional fluids, vasopressors, or inotropic agents should be made according to the clinical needs of the patient and the data obtained from hemodynamic and global and regional perfusion monitoring.[1,2,20,25–28,39]

ABBREVIATIONS

ACTH	adrenocorticotropic hormone
AT	angiotensin
ATP	adenosine triphosphate
BP	blood pressure
CaMK	calcium/calmodulin-dependent protein kinases
cAMP	cyclic adenosine monophosphate
CaO_2	arterial oxygen content
CI	confidence interval

CO	cardiac output
CvO_2	venous oxygen content
CVP	central venous pressure
D	dopamine
DO_2	oxygen delivery
HR	heart rate
ICU	intensive care unit
IL	interleukin
iNOS	inducible nitric oxide synthase
MAP	mean arterial blood pressure
NO	nitric oxide
O_2ER	oxygen extraction ratio
PaO_2	partial pressure of arterial oxygen
PAOP	pulmonary artery occlusion pressure
PLC	phospholipase C
RR	respiratory rate
SBP	systolic blood pressure
$ScvO_2$	central venous oxygen saturation
SvO_2	(mixed) venous oxygen saturation
SVR	systemic vascular resistance
TNF	tumor necrosis factor
V	vasopressin
VO_2	oxygen consumption

SELF-ASSESSMENT QUESTIONS

1. Which of the following conditions can result in a lowering of blood pressure in critically ill patients?

A. Increased cardiac output

B. Increased cardiac preload

C. Systemic vasodilation

D. Systemic vasoconstriction

2. The “lethal triad” associated with substantial blood loss is comprised of which of the following parameters?

A. Acidosis, hyperthermia, coagulopathy

B. Acidosis, hypothermia, coagulopathy

C. Alkalosis, hyperthermia, apoptosis

D. Alkalosis, hypothermia, necrosis

3. Which of the following hemodynamic profiles is typically observed in a patient with obstructive shock?

A. Low preload, low cardiac output, low afterload

B. Low preload, low cardiac output, high afterload

C. High preload, low cardiac output, low afterload

D. High preload, low cardiac output, high afterload

4. Based on efficacy and cost considerations, which of the following is the initial fluid of choice for the initial resuscitation of a patient with hypovolemic shock?

A. Lactated Ringer’s solution

B. Dextrose 5%

C. Albumin 5%

D. Albumin 25%

5. If given in large but equivalent volumes, which of the following fluids is most likely to yield hyponatremia?

A. 0.9% sodium chloride

B. Lactated Ringer’s solution

C. Albumin 5%

D. Albumin 25%

6. Stimulation of the beta-adrenergic receptor by agonists results in a physiologic response mediated by which of the following?

A. Inositol trisphosphate

B. Cyclic AMP

C. Cyclic GMP

D. Diacylglycerol

7. Which of the following drugs predominantly stimulates alpha-adrenergic receptors with minimal effects on beta-adrenergic receptors?

A. Dopamine

B. Phenylephrine

C. Epinephrine

D. Norepinephrine

8. Which of the following explains the development of lactic acidosis by a catecholamine?

A. Enhanced vasodilation in peripheral arteries

B. Enhanced glycogenolysis

C. Increased DO_2 to the liver

D. Increased cardiac output

9. Which of the following catecholamines is preferred as the initial agent when treating hypotension in a patient with septic shock?

A. Norepinephrine

B. Dobutamine

C. Dopamine

D. Phenylephrine

10. Which adverse drug effect is *not* observed with dobutamine?

A. Tachycardia

B. Bradycardia

C. Hypotension

D. Dysrhythmias

11. Which of the following is *least likely* to cause a tachyarrhythmia?

A. Epinephrine

B. Dopamine

C. Norepinephrine

D. Vasopressin

12. Which of the following adverse effects has been observed with angiotensin II?

A. Bradycardia

B. Thrombosis

C. Hyperbilirubinemia

D. Dysrhythmias

13. Which of the following is *true* regarding the use of vasopressin?

A. Studies have shown that it reduces mortality in patients with vasodilatory/distributive shock after cardiac surgery.

B. Studies have shown that it reduces organ dysfunction when initiated as the first-line agent for septic shock.

C. Studies have shown that it increases blood pressure while reducing the dose of other vasopressors when it is added to vasopressors.

D. Studies have shown that it increases the risk for atrial fibrillation.

14. Which of the following best summarizes current evidence comparing blood pressure control and tachyarrhythmias between dopamine and norepinephrine in patients with septic shock?

A. Dopamine may achieve better blood pressure control, tachyarrhythmias are less frequent.

B. Norepinephrine may achieve better blood pressure control, tachyarrhythmias are less frequent.

C. Norepinephrine may achieve better blood pressure control, tachyarrhythmias are more frequent.

D. Both agents achieve good blood pressure control, tachyarrhythmias are rare.

15. Which of the following receptors is most likely to cause an increase in heart rate when stimulated?

A. AT-2

B. β_1

C. V_1

D. α_1

16. Extravasation of a vasopressor catecholamine can be treated with intradermal injections of which of the following agents?

A. Phentolamine

B. Phenylephrine

C. Nitric oxide

D. Vasopressin

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** A lowering of blood pressure may be caused by any of reduced cardiac preload, reduced cardiac output, or decreased cardiac afterload (from systemic vasodilation) or a combination of these factors. See the “Pathophysiology” section for more information.

2. **B.** The “lethal triad” of hemorrhagic shock includes acidosis, hypothermia, and coagulopathy. See the “Pathophysiology” section for more information.

3. **D.** Obstructive shock is typically associated with a hemodynamic profile of high preload, low cardiac output, and high afterload. See the “Pathophysiology” section and Fig. e42-2 for more information.

4. **A.** Isotonic crystalloid solutions (such as lactated Ringer’s solution) are the initial fluid of choice for resuscitation based on efficacy and cost considerations. Dextrose 5% is not an isotonic crystalloid solution and does not effectively expand the intravascular space; therefore, it is not considered a fluid for resuscitation. See the “Treatment” (Pharmacologic Therapy) section and Table e42-2 for more information.

5. **B.** Lactated Ringer’s solution has 130 mEq/L (mmol/L) of sodium and therefore may cause hyponatremia if given in large volumes. See the “Treatment” (Pharmacologic Therapy) section and Table e42-3 for more information.

6. **B.** Beta-adrenergic receptor agonism is mediated through cyclic AMP. See the “Treatment” (Pharmacologic Therapy) section and Fig. e42-4 for more information.

7. **B.** Phenylephrine predominantly stimulates alpha-adrenergic receptors with minimal beta-adrenergic effects. The other agents stimulate beta-adrenergic receptors with at least moderate activity. See the “Treatment” (Pharmacologic Therapy) section and Table e42-5 for more information.

8. **B.** Potential mechanisms for catecholamine-associated lactic acidosis include enhanced vasoconstriction in peripheral arteries, enhanced glycogenolysis, and mobilization of lactate from peripheral tissues. See the “Treatment” (Pharmacologic Therapy) section for more information.

9. **A.** Norepinephrine is the preferred initial agent for most shock states, including septic shock. See the “Treatment” (Pharmacologic Therapy) section for more information.

10. **B.** Dobutamine has been associated with each of the listed adverse drug reactions except bradycardia. See the “Treatment” (Pharmacologic Therapy) section and Table e42-5 for more information.

11. **D.** Vasopressin does not have chronotropic effects and is, therefore, the least likely of the agents listed to cause a tachyarrhythmia. See the “Treatment” (Pharmacologic Therapy) section and Table e42-5 for more information.

12. **B.** Angiotensin II has been associated with thrombosis. See the “Treatment” (Pharmacologic Therapy) section and Table e42-5 for more information.

13. **C.** When vasopressin is added to other vasopressors it has been shown to improve blood pressure and decrease the dose of other vasopressors. See the "Treatment" (Pharmacologic Therapy) section for more information.

14. **B.** Norepinephrine is associated with better blood pressure control and less frequent tachyarrhythmias than dopamine. See the "Treatment" (Pharmacologic Therapy) section for more information.

15. **B.** Stimulation of β_1 (and AT-1) receptors is likely to cause an increase in heart rate. See the "Treatment" section and Table e42-1 for more information.

16. **A.** Phentolamine is an α-receptor antagonist that can be used to treat the extravasation of a vasopressor catecholamine. See the "Treatment" (Pharmacologic Therapy) section for more information.

Chapter e43: Evaluation of Respiratory Function

Megan L. Carreon; Maria I. Velez; Stephanie M. Levine; Jay I. Peters

KEY CONCEPTS

KEY CONCEPTS

① The function of the lungs is to maintain the arterial partial pressure of oxygen (PaO_2) and arterial partial pressure of carbon dioxide ($PaCO_2$) within normal ranges (ie, normal ventilation-perfusion ratio).

② The air in the lung is divided into four compartments: tidal volume—air exhaled during non- exertional breathing; inspiratory reserve volume (IRV)—maximal air *inhaled* above tidal volume; expiratory reserve volume (ERV)—maximum air *exhaled* after tidal volume; and residual volume (RV)—air remaining in the lung after maximal exhalation. The sum of all four components is the total lung capacity (TLC). Pulmonary function tests will produce values consistent with normal lungs or an obstructive or restrictive disease: recognition of these values is key.

③ Obstructive lung disease is defined as an inability to get air out of the lung. It is identified on spirometry when forced expiratory volume in the first second of expiration (FEV_1) compared to the forced vital capacity (FVC) (total amount of air that can be exhaled during a forced exhalation) (FEV_1/FVC) is less than 70% to 75% (0.70-0.75) in adults (or below the lower limit of normal (LLN) based on population studies).

④ An increase in FEV_1 of 12% (and greater than 0.2 L in adults) after an inhaled β-agonist suggests an acute bronchodilator response.

⑤ Restrictive lung disease is defined as an inability to get enough air into the lung and is best defined as a reduction in TLC (usually less than 80% of predicted).

⑥ Restrictive lung disease can be produced by a number of diseases, such as increased elastic recoil (interstitial lung disease), respiratory muscle weakness (myasthenia gravis), and mechanical restrictions (pleural effusion or kyphoscoliosis). It can also be the result of poor effort during the pulmonary function tests (PFTs).

⑦ The shape of the flow-volume loop, which includes inspiratory and expiratory flow-volume curves, and the ratio of forced expiratory and inspiratory flow at 50% of VC ($FEF_{50\%}/FIF_{50\%}$ greater than 1) may be useful in the diagnosis of upper airway obstruction.

⑧ Cardiopulmonary exercise testing allows for the assessment of multiple organs involved in exercise.

⑨ Spirometry and other pulmonary function tests in children are possible and can successfully be done with proper coaching methods and modified reference values.

INTRODUCTION

The primary function of the respiratory system is to maintain normal arterial blood gases, that is, arterial partial pressure of oxygen (PaO_2) and arterial partial pressure of carbon dioxide ($PaCO_2$). To achieve this goal, several processes must be accomplished; including alveolar ventilation, pulmonary perfusion, ventilation-perfusion matching, and gas transfer across the alveolar-capillary membrane. Alveolar ventilation is achieved by the cyclic process of air movement in and out of the lung. During inspiration, the inspiratory muscles contract and generate a negative pressure in the pleural space. This pressure gradient between the mouth and the alveoli draws fresh air (tidal volume [V_T]) into the lung. Approximately one-third of the inspired gas stays in the conducting airways (dead space), and two-thirds reach the alveoli.

① The human lung contains a series of branching, progressively tapering airways that originate at the glottis and terminate in a matrix of thin-walled alveoli. Coursing through this matrix of alveoli is a rich network of capillaries that originates from the pulmonary arterioles and terminates in the pulmonary venules. The adequacy of respiration in each gas exchange unit depends on the apposition of a thin film of mixed venous blood with just the right amount of fresh alveolar gas. During “ideal” gas exchange, blood flow and ventilation are uniform; accordingly, there is no alveolar-arterial difference (or gradient) in the partial pressure of oxygen ($P[A–a]O_2$, sometimes called the A–a gradient). However, gas exchange is not perfect, even in the normal lung. Normally, alveolar ventilation is less than pulmonary blood flow, and the overall ventilation-perfusion ratio is 0.8 (not 1.0).

Normal expiration is a passive process, and when the inspiratory muscles end their contraction, the elastic recoil of the lung pulls the lung back to its original size and shape. This process makes the alveolar pressure positive relative to the pressure at the mouth, and air flows out of the lung. During inspiration, the respiratory muscles must overcome the elastic properties of the lung (elastic recoil) and the resistance to air flow by the airways. During expiration, the flow of air is determined primarily by the elastic recoil and airway resistance.

Different pulmonary function tests (PFTs) are used to evaluate the physiologic processes of the respiratory system. Abnormalities that can be measured by pulmonary function testing include obstruction to airflow, changes in lung size, and decreases in the transfer of gas across the alveolar-capillary membrane. Spirometry is frequently used to screen patients for evidence of obstruction or restrictive lung disease when they present with respiratory complaints. Normal PFTs values are obtained from a group of normal individuals based on age, height, sex, and race. A PFT is considered abnormal when the results fall outside the range found in 95% of people of the same age, height, and sex (95% confidence interval). This definition is arbitrary and may misclassify a small percentage of normal individuals as having lung dysfunction; it may also miss patients with mild pulmonary disease. Therefore, clinical correlation and serial pulmonary function testing may be necessary for optimal interpretation of PFTs.

Potential uses of pulmonary function testing include evaluation of patients with known or suspected lung disease; evaluation of symptoms such as chronic cough, dyspnea, or chest tightness; monitoring of the effects of exposure to dust, chemicals, or pulmonary toxic drugs; risk stratification prior to surgery; monitoring of the effectiveness of therapeutic interventions; and objective assessment of impairment or disability.[1]

DEFINITIONS OF LUNG VOLUMES AND EXPIRATORY FLOWS

② The air within the lung at the end of a forced inspiration can be divided into four compartments or lung volumes (Fig. e43-1). The volume of air exhaled during normal quiet breathing is the V_T. The maximal volume of air inhaled above V_T is the *inspiratory reserve volume* (IRV), and the maximal air exhaled below V_T is the *expiratory reserve volume* (ERV). The *residual volume* (RV) is the amount of air remaining in the lungs after a maximal exhalation.

FIGURE e43-1

Lung volumes and capacities. (ERV, expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; IRV, inspiratory reserve volume; RV, residual volume; TLC, total lung capacity; VC, vital capacity; V_T, tidal volume)

The combinations or sums of two or more lung volumes are termed *capacities* (see Fig. e43-1). *Vital capacity* (VC) is the maximal amount of air that can be exhaled after a maximal inspiration. It is equal to the sum of IRV, V_T, and ERV. When measured on a forced expiration, it is called the *forced vital capacity* (FVC). When measured over an exhalation of at least 30 seconds, it is called the *slow vital capacity* (SVC). The VC is approximately 75% of the *total lung capacity* (TLC), and when the SVC is within the normal range, a significant restrictive disorder is unlikely. Normally, the values for SVC and FVC are very similar unless airway obstruction is present.

Total lung capacity (TLC) is the volume of air in the lung after a maximal inspiration and is the sum of the four primary lung volumes (IRV, V_T, ERV, and RV). Its measurement is difficult because the amount of air remaining in the chest after maximal exhalation, RV, must be measured by indirect methods. The definition of restrictive lung disease is based on a reduction in TLC (ie, an inability to get air into the lung or restriction to air movement during inhalation).

The *functional residual capacity* (FRC) is the volume of air remaining in the lungs at the end of a quiet expiration. It is the sum of RV and ERV. FRC is the normal resting position of the lung; it occurs when there is no contraction of either inspiratory or expiratory muscles and normally is 40% of TLC. *Inspiratory capacity* (IC) is the maximal volume of air that can be inhaled from the end of a quiet expiration and is the sum of V_T and IRV.

FVC, which represents the total amount of air that can be exhaled, can be expressed as a series of timed volumes. The *forced expiratory volume in the first second of expiration* (FEV_1) is the volume of air exhaled during the first second of the FVC maneuver. Although FEV_1 is a volume, it conveys information on obstruction because it is measured over a known time interval. FEV_1 depends on the volume of air within the lung and the effort during exhalation; therefore, it can be diminished by a decrease in TLC or by a lack of effort. A more sensitive way to measure obstruction is to express FEV_1 as a ratio of FVC. This ratio is independent of the patient's size or TLC; therefore, FEV_1/FVC is a specific measure of airway obstruction with or without restriction. Normally, in adults older than 20 years this ratio is greater than or equal to 80% (0.80), and any value less than 80% to 75% (0.80-0.75) suggests obstruction. In children and young adults (age 5-20 years), an FEV_1/FVC ratio less than or equal to 85% (0.85) is considered a sign of obstruction.[2]

Flow is defined as the change in volume with time, forced expiratory flow (FEF) can be determined graphically by dividing the volume change by the time change. The *FEF during 25% to 75% of FVC*($FEF_{25\%\text{-}75\%}$) represents the mean flow during the middle half of the FVC. $FEF_{25\%\text{-}75\%}$, formerly called the *maximal mid-expiratory flow*, is used frequently in the assessment of small airways. The *peak expiratory flow* (PEF), also called *maximum forced* *expiratory flow* (FEF_{max}), is the maximum flow obtained during FVC. This measurement is used often in the outpatient management of asthma because it can be measured with inexpensive peak flow meters.

All lung volumes and flows are compared with normal values obtained from healthy subjects. There are significant ethnic and racial variations in normal values, and all PFTs should report that race/ethnic adjustment factors have been used. This is especially important in African American subjects who exhibit a greater proportion of their height in the waist-to-leg length. If not corrected for race/ethnicity, many subjects will have restrictive lung functions. The 2005 American Thoracic Society–European Respiratory Society (ATS–ERS) guidelines for interpretation of PFT results recommended that, for spirometry in the United States, the National Health and Nutrition Examination Survey (NHANES) III reference be used for subjects aged 8 to 80 years and the Wang equation used in subjects younger than 8 years.[3] In 2012, an ERS task force called the Global Lung Initiative (GLI), released spirometry reference equations that were based on over 90,000 spirometry results collected worldwide from healthy, nonsmoking individuals aged 3 to 95 years and from different ethnicities with the purpose to provide a continuous spirometry reference range that spanned all ages. The reference equations obtained from this initiative provide the most reliable spirometric prediction and therefore have been endorsed by all major international respiratory societies.[4]

Depending on the classification of the disease state that the patient may have, you should expect to see a difference between the values. A patient's pulmonary function tests will produce values consistent with normal lungs or with obstructive or restrictive disease. Figure e43-2 depicts how different restrictive and obstructive lung diseases affect the lung volumes and capacities in relation to normal lung volumes and capacities.

FIGURE e43-2

Lung volumes and capacities—normal vs restrictive and obstructive lung diseases.

Spirometry/Flow-Volume Loop

Spirometry is the most widely available and useful PFT.[5] The test takes only 15 to 20 minutes to perform, carries minimal risks, and provides information about obstructive and restrictive disease. Spirometry allows for the measurement of all lung volumes and capacities except RV, FRC, and TLC; it also allows the assessment of FEV_1 and $FEF_{25\%-75\%}$. During the test, patients are asked to take a maximal inspiration and forcefully exhale.

Spirometry measurements can be reported in two different formats—standard spirometry (Fig. e43-3) and the flow-volume loop (Fig. e43-4). In standard spirometry, the volumes are recorded on the vertical (*y*) axis and the time on the horizontal (*x*) axis. In flow-volume loops, the volume is plotted on the horizontal (*x*) axis, and flow (derived from volume/time) is plotted on the vertical (*y*) axis. The shape of the flow-volume loop can be helpful in differentiating obstructive and restrictive defects and in diagnosing upper airway obstruction (Fig. e43-5). This curve gives a visual representation of obstruction, where the expiratory descent becomes more concave (Fig. e43-5 Panel B). The spirometry should be performed three times to ensure that the results are reproducible (less than 200 cc variation).

FIGURE e43-3

Standard spirometry. Curve 1 is for a normal subject with normal FEV_1; curve 2 is for a patient with mild airway obstruction; curve 3 is for a patient with moderate airway obstruction; curve 4 is for a patient with severe airway obstruction.

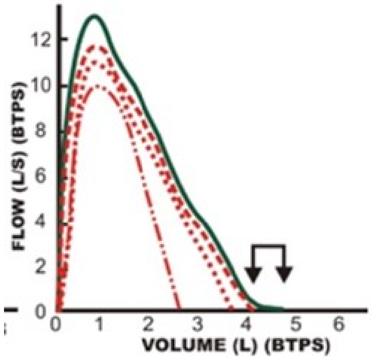
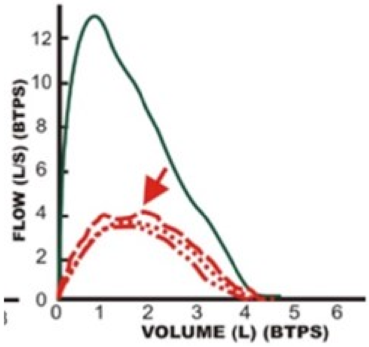
Spirometry is an indicator and foundational starting point to properly diagnosing and developing a treatment plan based on results, but the accuracy of the results is a priority. When performing spirometry, adequately coaching the patient from beginning to end is necessary. There are common problems that occur when spirometry is performed, which must be identified in order to properly diagnose and treat patients. Some of the most common issues that you will see include the following: normal curves are represented by the green curve and red curves represent the issue).[6]

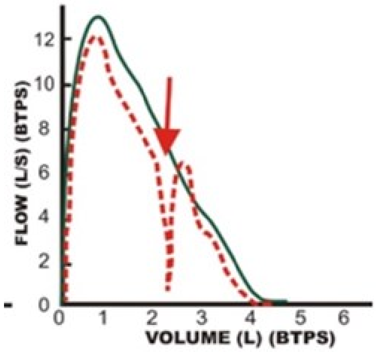
- **Sub-maximal inhalation—**An incomplete inhalation is a serious problem that frequently occurs.



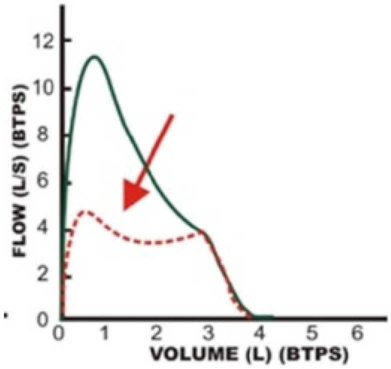
- **Sub-maximal blast**—When a patient fails to blast out fast and hard at the beginning of a test, the results will produce falsely low numbers, possibly leading to an inaccurate diagnosis. Recognition of this problem is best seen at the peak of the curve. You will see that it does not form a sharp peak, but instead creates a decreased and rounded curve.



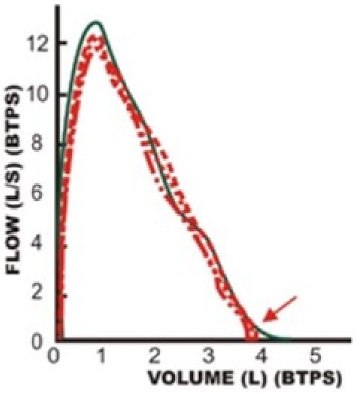
- **Coughing within the first second of exhalation**—Coughing in the first second of the blast-out creates a high probability for the FEV_1 measurement to be analyzed incorrectly. This is best seen in the deep dip occurring immediately after the peak.



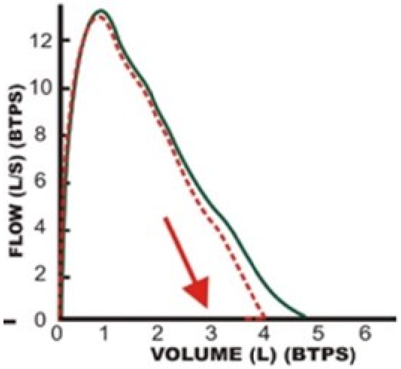
- **Variable efforts**—Variable efforts are patient-dependent and can commonly be corrected with adequate coaching from the clinician. You typically see this when the patient is not blasting out at one speed, but instead consistently exhales into the spirometer at changing flows. You will recognize this in the curve when it fails to reach a peak and creates a more flat curve.



- **Early termination**—When performing spirometry, the patient must exhale for a minimum of 6 seconds. If the patient ends the blast-out early that attempt cannot be utilized to diagnose and treat the patient. Early termination can best be seen in the curve when it drops down to zero prior to plateauing on the baseline.



- **Leaks**—Leaks can be found within the spirometer, the mouthpiece, and also the patient. If you find that your machinery and mouthpiece are functioning well with no leaks, check the patient. Look for a good mouth seal and nose piercings (these can create a leak) and ensure that nose clips are being worn. You will recognize leaks as the curves drop off to baseline and begin to run back toward zero.



Contraindications to performing PFTS include myocardial infarction within the last month, unstable angina, recent thoracoabdominal surgery recent ophthalmic surgery, thoracic or abdominal aneurysm, and current pneumothorax.

Lung Volumes

Spirometry measures three of the four basic lung volumes but cannot measure RV. RV must be measured to determine TLC. TLC should be measured anytime; VC is reduced in order to confirm or exclude the presence of restriction. The four methods for measuring TLC are helium dilution, nitrogen washout, body plethysmography, and chest x-ray measurement (planimetry).[7] The first two methods are called *dilution techniques* and only measure lung volumes in communication with the upper airway. In patients with airway obstruction who have trapped air, dilution techniques will underestimate the actual volume of the lungs. Planimetry measures the circumference of the lungs on the posteroanterior and lateral views of a chest x-ray film and estimates the total lung volume.

Body plethysmography, or body box, is the most accurate technique for lung volume determinations. It measures all the air in the lungs, including trapped air. The principle of the measurement of the body box is Boyle's gas law ($P_1V_1 = P_2V_2$): a volume of gas in a closed system varies inversely with the pressure applied to it. The changes in alveolar pressure are measured at the mouth, as well as pressure changes in the body box. The volume of the body box is known. Lung volumes can be determined by measuring the changes in pressures caused by panting against a closed shutter. The measurement of lung volumes provides useful information about the elastic recoil of the lungs. If elastic recoil is increased (as in interstitial lung disease), lung volumes (TLC) are reduced. When elastic recoil is reduced (as in emphysema), lung volumes are increased.

OTHER PULMONARY FUNCTION TESTS

Carbon Monoxide Diffusing Capacity

The diffusing capacity of the lungs (D_L) is a measurement of the ability of a gas to diffuse across the alveolar-capillary membrane.[8] Carbon monoxide is the usual test gas because normally it is not present in the lungs and is much more soluble in blood than in lung tissue. When the diffusing capacity is determined with carbon monoxide, the test is called the *diffusing capacity of lung for carbon monoxide* (DLCO). Because DLCO is directly related to alveolar volume (V_A), it is frequently normalized to the value D_L/V_A, which allows for its interpretation in the presence of abnormal lung volumes (ie, after surgical lung resection).

The diffusing capacity will be reduced in all clinical situations where gas transfer from the alveoli to capillary blood is impaired. Common conditions that reduce DLCO include lung resection, emphysema (loss of functioning alveolar-capillary units), and interstitial lung disease (thickening of the alveolar-capillary membrane). Normal spirometry and lung volumes with reduced DLCO should suggest the possibility of pulmonary vascular disease (eg, pulmonary embolus and pulmonary hypertension), anemia, or early interstitial lung disease.

Pulmonary Gas Exchange

The essential function of the lungs is to maintain blood gas homeostasis. Arterial blood gas measurement plays an important role in the diagnosis and management of patients with pulmonary disease and should be ordered whenever hypoxemia, hypercapnia (CO_2 retention), and/or acid-base disorders are suspected clinically. Every time arterial blood gas determinations are ordered, the A–a gradient (the difference between partial pressure of oxygen [PO_2] in the alveolus and PO_2 in arterial blood) should be calculated. This is accomplished by computer on all automated blood gas machines, and a normal $P(A–a)O_2$ can be calculated using the formula (age/4) + 4 or 2.5 (0.21 × age). The presence of hypoxemia with a normal A–a gradient usually implies alveolar hypoventilation (eg, sedative overdose). Most patients develop hypoxemia secondary to mismatching of ventilation and perfusion, and $P(A–a)O_2$ will be significantly elevated.

Oxygen saturation as measured by pulse oximetry (SpO_2) is widely used in clinical practice for monitoring arterial saturation. A pulse oximeter is a small battery-operated device that is placed on the finger or the earlobe. The device emits and reads the reflected light from capillary blood and estimates the saturation. Although SpO_2 is clinically useful, SpO_2 is only an estimate of arterial saturation. Actual arterial oxygen saturation (SaO_2) can be ±2% to 4% (0.02-0.04) of the oximetry reading. The error may be even greater with saturation less than 80% (0.80). Pulse oximeters do not measure carboxyhemoglobin, and SpO_2 may be overestimated significantly in patients with smoke inhalation or in smokers. Initial validation of pulse oximetry with direct measurement of SaO_2 is recommended in any critically ill patient.

Exercise Testing

Cardiopulmonary exercise testing allows for the assessment of multiple organs involved in exercise and has benefits over assessments of either the cardiac system or pulmonary system alone. The major indications for exercise testing are to determine exercise capacity, evaluate dyspnea on exertion, evaluate exercise-induced bronchospasm, and assess suspected arterial desaturation during exercise.[9–13] Exercise testing can also be useful in the evaluation of ventilatory or cardiovascular limitations to work, assessment of general fitness or conditioning, evaluation of disability, the establishment of safe levels for exercise, evaluation of drug therapy, determining the need and liter flow for supplemental oxygen therapy during exercise, assessment of the effects of a rehabilitation program, and preoperative assessment before lung resection.[9–15]

Tests for general fitness include the 6-minute walking distance and the Harvard step test[10,12]. For the 6-minute walking distance, the subject simply walks a predetermined route or circuit as fast as possible for 6 minutes. The subject is allowed to stop and rest, but the clock continues to run. The greater the distance covered, the better the patient's general fitness and exercise tolerance. For healthy elderly subjects, a distance of 631 ± 93 m is considered normal and a change of 54 m in between tests is considered significant. For the Harvard step test, the subject steps up and down on a 20-in. (51 cm) step at a set rate for 5 minutes. A 1-minute rest period is followed by a measurement of the subject's recovery heart rate. The lower the recovery heart rate time, the better the subject's general fitness.

Exercise testing is performed to determine if exercise results in arterial oxygen desaturation (drop in oxygen saturation >4% [0.04] with physical activity).[10,11] The test may be useful for quantifying the level of exertion the patient can perform during the activities of daily living as well as determining appropriate levels of supplemental oxygen therapy. Typically, this test is done using a treadmill or cycle ergometer. A baseline measurement of arterial blood gas values or pulse oximetry is followed by up to 6 minutes of exercise, during which time the patient is monitored for oxygen desaturation using pulse oximetry. If significant desaturation occurs (saturation less than 88% [0.88]), the test is terminated. In the event of oxygen desaturation, the test can be repeated to determine the level of supplemental oxygen therapy needed to compensate for the desaturation that otherwise would occur.

When more formal exercise testing is needed for some of the indications previously listed (eg, dyspnea evaluation, evaluation of ventilatory or cardiovascular limitations to work, evaluation of disability, and preoperative assessment before lung resection), exercise tolerance tests or cardiopulmonary stress testing can be performed. Tests include the measurement of oxygen consumption ($\dot{V}O_2$VO2), carbon dioxide production ($\dot{V}CO_2$ VCO2), minute volume (V E), tidal volume (V_T), respiratory rate, SpO_2, heart rate, blood pressure, and recording or monitoring of the electrocardiogram. Exercise increases workload in a linear fashion until a maximum oxygen consumption level ($\dot{V}CO_{2max}$VCO2max) is reached. Consequently, VO_{2max} is a measure of an individual's muscular work capacity.[9–13] Normal is approximately 1,700 mL/min (28 mL/s) for a sedentary person and up to 5,800 mL/min (97 mL/s) for a trained athlete.[16] This compares with a resting VO_{2max} of approximately 250 mL/min (4.1 mL/s). Ventilatory equivalents for oxygen, carbon dioxide, and O_2 pulse are often calculated. The ventilatory equivalent for oxygen is a measure of the efficiency of the ventilatory pump at various workloads.[9,11,12]

O_2 pulse is an estimate of oxygen consumption per cardiac cycle and can be decreased with cardiac problems. A normal O_2 pulse is 2.5 to 4 mL/beat at rest and increases to 10 to 15 mL/beat during strenuous exercise.[9–11]

The anaerobic threshold is the point during strenuous exercise at which anaerobic metabolism and lactic acid production begin.[9,11,12] CO_2 increases with exercise at about the same rate until the subject's anaerobic threshold is reached. From that point on, CO_2 increases faster than O_2, and this change can be used to estimate the anaerobic threshold. A breath-by-breath plot of the ventilatory equivalents for O_2 and CO_2 also can be used to determine the anaerobic threshold. Anaerobic threshold is a measure of fitness in normal subjects, and aerobic training can delay the anaerobic threshold.[9,11]

For exercise tolerance testing, the patient typically is subjected to either a constant workload (steady-state tests) or an increasing workload (progressive multistage tests) using a cycle ergometer or treadmill.[9,11] With progressive multistage tests, the patient exercises to exhaustion or the occurrence of an adverse reaction, at which point the test is stopped. Safety during exercise testing is of major importance, and rigorous guidelines for the termination of the test should be followed. Both types of tests can be used to determine. A limit to exercise, as indicated by a decrease in, can result from (a) poor conditioning, (b) pulmonary limitation, (c) cardiac limitation, or (d) poor effort. In the case of poor conditioning, SpO_2 and O_2 pulse will be normal. With a pulmonary limitation to exercise, SpO_2 will be reduced and O_2 pulse will be normal or reduced. With a cardiac limitation to exercise, SpO_2 will be normal and O_2 pulse will be reduced.

Table e43-1 summarizes the indications and contraindications for exercise testing. Table e43-2 summarizes the findings during maximum exercise associated with poor conditioning, pulmonary limitations to exercise, and cardiac limitations to exercise.

TABLE e43-1

Indications and Contraindications for Exercise Testing

Indications

- Dyspnea on exertion
- Exercise-induced bronchospasm
- Suspected arterial desaturation with exercise
- Evaluation of ventilatory limitations to exercise
- Evaluation of cardiac limitations to exercise
- Assessment of general fitness or conditioning
- Evaluation of cardiopulmonary disability
- Establishment of safe levels for exercise
- Evaluation of drug therapy
- Determining appropriate use of supplemental oxygen therapy
- Establishing an exercise prescription for a rehabilitation program
- Assessment of the effect of a rehabilitation program
- Evaluation of specific disease states or conditions (eg, asthma, chronic obstructive pulmonary disease [COPD], interstitial lung disease, pulmonary vascular disorders, coronary artery disease, other vascular disorders, neuromuscular disorders, obesity, an xiety-induced hyperventilation)
- Assessment before resection
- Assessment before lung volume reduction surgery or lung transplantation

Contraindications

- PaO_2 <40 mm Hg (5.3 kPa) on room air $PaCO_2$ >70 mm Hg (9.3 kPa)
- FEV_1 <30% of predicted
- Recent (within 4 weeks) myocardial infarction, unstable angina pectoris
- Second- or third-degree heart block, rapid ventricular/atrial arrhythmias, orthopedic impairment
- Severe aortic stenosis, congestive heart failure, uncontrolled hypertension, limiting neurologic disorders
- Dissecting/ventricular aneurysms, severe pulmonary hypertension
- Thrombophlebitis or intracardiac thrombi
- Recent systemic or pulmonary embolus
- Acute pericarditis

TABLE e43-2

Typical Findings During Maximum Exercise with Poor Conditioning, Pulmonary Limitations to Exercise, and Cardiac Limitations to Exercise

Test Parameter	Poor Conditioning	Pulmonary Limitation	Cardiac Limitation
$\dot{V}CO_{2max}$VCO2max	↓	↓	↓
SpO_2	N	↓	N
O_2 pulse	N or ↓	N or ↓	↓
Anaerobic threshold	↓ or N	↓ or N	↓
Ventilatory reserve[a] (MVV – V_{Emax})	N	↓	N or ↓

N, normal.

[a] Ventilatory reserve = maximum voluntary ventilation (MVV) – minute volume during maximum exercise (V_{Emax}).

Respiratory Muscle Function

The maximum inspiratory pressure (MIP) and maximal expiratory pressure (MEP) are indirect measures of the respiratory muscles' function. During these tests, patients are asked to take a maximum breath, on inhalation for MIP and on exhalation for MEP, against a closed valve. The pressure measured during these maneuvers reflects the pressure developed by the respiratory muscles, plus the passive elastic recoil pressure of the respiratory system including the lung and chest wall. These tests can be of use in assessing the severity, functional consequences, and progress of patients with neuromuscular diseases.[15] The following table lists the ranges of normal values based on age and gender.[14]

Age	7-13 years	13-35 years	18-65 years	65-85 years
Male	MIP: −77 to −114	MIP: −114 to −121	MIP: −92 to −121	MIP: −65 to −90
	MEP: 99 to 161	MEP: 92 to 95	MEP: ≈140	MEP: 140 to 190
Female	MIP: −71 to −108	MIP: −65 to −85	MIP: −68 to −79	MIP: −71 to −108
	MEP: 74 to 126	MEP: 92 to 95	MEP: ≈95	MEP: 90 to 130

Another respiratory muscle function test commonly utilized is the sniff nasal inspiratory pressure (SNIP). This maneuver is done by wedging a bung into one nostril, through which a thin catheter connected to a pressure transducer has been passed (completely obstructs flow through that nostril).[14] The clinician will instruct the patient to "sniff" (inhale through the unobstructed nostril as strong as possible) and the pressure will be measured producing the value that represents the inspiratory muscle strength.

Producing the results for the three mentioned muscle function tests above is highly dependent on patient effort and may produce inaccurate results without proper cooperation. The clinician's enthusiasm efforts, encouragement methods, attitude, and coaching are great contributors to the results obtained.

Impulse Oscillometry

Impulse Oscillometry is a non-invasive test in which pressure oscillations are applied at the mouth to measure pulmonary resistance and reactance of the total respiratory system. This technique is effort independent and requires minimal cooperation, which is a major advantage in testing children, older adults, and patients with physical or intellectual disabilities. This test has not been applied to large populations to generate predicted values, and in some cases, the endpoints show high variability, therefore, is not as widely used as spirometry in the adult population.[17]

Fractional Exhaled Nitric Oxide

According to the ATS clinical practice guidelines,[16] the measurement of fractional nitric oxide (NO) concentration in exhaled breath (FENO) is a quantitative, noninvasive, simple, and safe method of measuring eosinophilic airway inflammation that provides a complementary tool to other ways of assessing airways disease, including asthma and its response to therapy (inhaled corticosteroids). A low FENO (<25 ppm) indicates that eosinophilic inflammation and response to inhaled steroids is less likely whereas increased FENO (>50 ppm) indicates responsiveness to corticosteroids.

There is wide variability in pulmonary function test reports among laboratories, the American Thoracic Society (ATS) recently released recommendations for the presentation of PFT results, recommendations from this statement include the standard report of reference values based on the GLI, display of normal limits for each test, report of barometric pressure, and a grading system for test quality.[18]

LUNG DISEASES

Obstructive Lung Disease

③ Obstructive lung disease implies a reduced capacity to get air through the conducting airways and out of the lungs. This reduction in airflow may be caused by a decrease in the diameter of the airways (bronchospasm decrease in driving pressure). The most common diseases associated with obstructive pulmonary functions are asthma, emphysema, and chronic bronchitis; however, bronchiectasis, infiltration of the bronchial wall by tumor or granuloma, aspiration of a foreign body, and bronchiolitis also cause obstructive PFTs. The standard test used to evaluate airway obstruction is spirometry.

Standard spirometry and flow-volume loop measurements include many variables; however, according to ATS guidelines, the diagnosis of obstructive and restrictive ventilatory defects should be made using the basic measurements of spirometry.[3,5] A reduction in FEV_1 (with normal FVC) establishes the diagnosis of obstruction. In restrictive lung disease, the patient has an inability to get air into the lung, which results in a reduction of all expiratory volumes (FEV_1, FVC, and SVC). In obstructed patients, a better measurement is the ratio FEV_1/FVC. Patients with restrictive lung disease have reduced FEV_1 and reduced FVC, but FEV_1/FVC remains normal. Although a normal FEV_1/FVC ratio is greater than 75% to 80% (0.75-0.80), the ratio is age-dependent, and slightly lower values may be normal in older patients. Younger children have increased lung elastic recoil and may have higher ratios. Children should have a FEV_1/FVC greater than or equal to 90% (0.90). According to the 2018 National Asthma Education and Prevention Program and the most recent Global Imitative for Asthma (GINA) guidelines, any value below this value should be considered a sign of obstruction, even if the FEV_1 and FVC are within the normal range.[2] Caution should be used in interpreting obstruction when FEV_1/FVC is below normal, but both FEV_1 and FVC are within the normal range because this pattern can be seen with healthy, athletic subjects as well as subjects with mild asthma. Clinical judgment and response to bronchodilator challenge are often required to separate out these two groups. In children, the improvement in FEV_1 often is the only way to document mild-to-moderate obstructive lung disease.

In screening spirometry performed in office practice, forced expiratory volume in 6 seconds (FEV_6) can be used in place of FVC. FEV_6 is a more reproducible number when obtained by less skilled personnel. The measurement of $FEF_{25\%-75\%}$ also is abnormal in patients with obstructive airways disease. This test has so much variability that it adds little to the measurement of FEV_1 and FEV_1/FVC.

Although there is no standardization for interpretation of the severity of obstruction, most pulmonary laboratories state that FEV_1/FVC less than 70%

(0.70) of the predicted value is diagnostic for obstruction, and the degree of obstruction is based on the percent predicted of FEV_1. FEV_1 between 80% and 100% of the predicted value is a mild obstruction, 79% and 50% of the predicted value is a moderate obstruction, 49% and 30% is consistent with severe obstruction, and less than 30% of the predicted value is classified as severe obstruction.[19] In patients with obstruction, a dose of a bronchodilator (eg, albuterol or isoproterenol) by metered-dose inhaler is given during the initial examination. An increase in FEV_1 greater than 12% and greater than 0.2 L suggests an acute bronchodilator response.[3,5] It is important to remember that bronchodilator responsiveness is variable over time, and therefore, the lack of an acute bronchodilator response should not preclude a short trial of albuterol and/or corticosteroids.

Although all patients with obstructive lung disease of any etiology will have reduced flow rates on forced exhalation, the pattern on PFTs may be helpful in differentiating among the various etiologies (Table e43-3). Asthma is characterized by variable obstruction that often improves or resolves with appropriate therapy. Because asthma is an inflammatory disorder of the airways (predominantly large airways), DLCO is usually normal or even slightly above the normal range. Most patients with acute asthma have a bronchodilator response greater than 15% to 20%; chronic bronchitis may be limited to the airways, but the vast majority of patients with chronic bronchitis and airway obstruction have a mixture of bronchitis and emphysema and have a reduction in DLCO. Therefore, DLCO is the best PFT for separating asthma from COPD.

TABLE e43-3

Specific Patterns of Pulmonary Function in Patients with Chronic Obstructive Pulmonary Disease

		COPD	
	Asthma	Chronic Bronchitis	Emphysema
Decreased FEV_1	++++	++++	++++
Decreased FEV_1/FVC	++++	++++	++++
Increased airway resistance	++++	++++	+
Decreased DLCO	–	–/++[a]	++++
Response to bronchodilators	++++	+[b]	–[b]

DLCO, diffusing capacity of lung for carbon monoxide; FEV_1, forced expiratory volume in the first second of expiration; FVC, forced vital capacity.

[a] Most smokers with chronic bronchitis have reduced DLCO.

[b] Twenty percent of patients with chronic obstructive pulmonary disease (COPD) have a large (++++) bronchodilator response.

A recently described entity asthma-COPD overlap syndrome (ACOS) encompasses patients with persistent airflow limitation as seen in COPD and several features typically associated with asthma including airway hyperresponsiveness and marked bronchodilator response. After the diagnosis of obstructive airways disease is established, the course and response to therapy are best followed by serial spirometry.

Airway Hyperreactivity

④ *Airway hyperreactivity* or *hyperresponsiveness* is defined as an exaggerated bronchoconstrictor response to physical, chemical, or pharmacologic stimuli. Individuals with asthma, by definition, have hyperresponsive airways. The Lung Health Study Research Group observed nonspecific hyperresponsiveness in a significant number of patients with COPD. This group of patients with airway hyperreactivity has a worse prognosis and an accelerated rate of decline in FEV_1.[20]

Some patients with asthma (especially cough-variant asthma) present with no history of wheezing and normal PFTs. The diagnosis of asthma still can be established by demonstrating hyperresponsiveness to provocative agents. The agents used most widely in clinical practice are methacholine and mannitol. Other agents used for bronchial provocation include distilled water, hypertonic saline, cold air, histamine, and exercise. Medications that can potentially affect the test giving false negative results include β2 agonist (short- and long-acting), antimuscarinic agents (short- and long-acting), theophylline, and leukotriene receptors antagonists[2] (Table e43-4). During a typical methacholine bronchoprovocation test, baseline FEV_1 is measured after inhalation of isotonic saline, and then increasing doses of methacholine are given at set intervals. Hyperresponsiveness is defined as a decline in FEV_1 greater than or equal to 20% and reversibility of obstruction to bronchodilators. The result can best be expressed as the provocative concentration needed to cause a 20% fall in FEV_1 (PC_{20}). A test is considered positive if methacholine demonstrates a PC_{20} less than or equal to 4 mg/mL or less than 60 to 80 cumulative breath units The test is considered negative if the PC_{20} is greater than 16 mg/mL. Values between 4 and 16 are considered borderline.[20] The bronchoprovocation tests (methacholine, mannitol test) is contraindicated in severe airway obstruction (FEV_1 less than 60% or 1.5 L), uncontrolled hypertension (SBP greater than 200 mm Hg and DBP greater than 100 mm Hg), recent myocardial infarction or cerebrovascular accident (in the 3 previous months), known aortic aneurysm and recent eye surgery or intracranial pressure elevation risk.[21]

TABLE e43-4

Recommended Time to Withhold Medication Prior to Bronchoprovocation Study

Medication Types	Recommended Time to Withhold Prior to Bronchoprovocation Study
Short-acting β2 agonist	8 hours
Inhaled corticosteroids	12 hours
Short-acting anticholinergics	12 hours
Inhaled corticosteroids plus long-acting β2 agonists	24 hours
Long-acting β2 agonists	24 hours
Theophylline	24 hours
Antihistamines	72 hours
Leukotriene-receptor antagonists	96 hours

Mannitol comes in inhaled dry-powder capsules of graduated doses, which makes its administration convenient.[22] When using mannitol, a drop in FEV_1 greater than or equal to 15% from baseline (0 mg) up to a dose of 635 mg or a 10% reduction in FEV_1 between consecutive doses is considered significant and is referred to as provocative dose 15 (PD15). This test is used most frequently to establish a diagnosis of asthma in patients with normal PFTs, but it also may be useful in following patients with occupational asthma, establishing the severity of asthma, and assessing the response to treatment.

Upper Airway Obstruction

Obstruction of airflow by abnormalities in the upper airway often goes undiagnosed or misdiagnosed because of improper interpretation of PFTs. Patients have obstructive physiology and often are misclassified as having asthma or COPD. The shape of the flow-volume loop, which includes inspiratory and expiratory flow-volume curves, and the ratio of forced expiratory and inspiratory flow at 50% of VC ($FEF_{50\%}/FIF_{50\%}$ greater than 1) may be useful in the diagnosis of upper airway obstruction.[3,23]

The shape of the flow-volume curve differs depending on whether the obstruction is fixed or variable (Fig. e43-5). Fixed lesions, as in strictures from previous intubations or tracheostomy, cause a uniform caliber of the airway during inspiration and expiration. With variable lesions, the airway caliber changes with changes in intrathoracic pressure. Variable lesions are sub-classified into variable intrathoracic and variable extrathoracic. If the lesion is intrathoracic, as with tumors of the trachea, the negative pressure generated during inspiration opens the obstruction, whereas the positive pressure during expiration worsens the obstruction. If the lesion is a variable extrathoracic obstruction, as with vocal cord dysfunction, the negative pressure within the airways will pull the vocal cord toward the midline and potentiate the obstruction. In this case, there will be a plateau on the inspiratory limb of the flow-volume loop, and $FEF_{50\%}/FIF_{50\%}$ will be greater than 1. Typical flow-volume curves from upper airway obstruction are shown in Fig. e43-6.

While 80% of subjects with vocal cord dysfunction demonstrate the classical variable extrathoracic pattern, 18% present with a pattern of variable intrathoracic obstruction, and 2% present with a pattern of fixed obstruction.

FIGURE e43-6

Maximum expiratory flow-volume curves from patients with fixed obstruction, variable extrathoracic obstruction, and variable intrathoracic obstruction. (RV, residual volume; TLC, total lung capacity.)

Restrictive Lung Disease

⑤ *Restrictive lung disease* is defined as an inability to get air into the lungs and to maintain normal lung volumes. Restrictive lung disease reduces all the subdivisions of lung volumes (IRV, TV, ERV, and RV) without reducing airflow. Patients have normal airway resistance and FEV_1/FVC greater than 70% (0.70). A combined consensus statement from the ATS and the ERS defines restrictive and obstructive disorders.[24]

Although *restriction* could be defined as a reduction in VC or FVC with normal FEV_1/FVC, poor effort also will reduce FVC with normal FEV_1/FVC. A reduction in TLC is the most accurate measurement of restrictive lung function. As discussed earlier, TLC can be measured by various techniques. The gas dilution methods (eg, helium dilution and nitrogen washout) are unable to measure gas trapped in cysts or bullae and may underestimate the true lung volume. Therefore, TLC is best measured by plethysmography. Most restrictive lung diseases are associated with impairment or destruction of the alveolar-capillary membrane; therefore, DLCO is reduced in most patients with restrictive lung disease. The reduction in DLCO may occur prior to a reduction in lung volumes and is used as a marker of early interstitial (restrictive) lung disease. DLCO may be abnormal even with a normal chest x-ray film, and thin-sliced high-resolution computed tomographic scans of the chest (HRCT = 0.625-1.5 mm thickness) or a CT with thin cuts (2-3 mm thickness) may be required to diagnose early interstitial lung disease. Because peribronchiolar inflammation and fibrosis occur in some patients with restrictive parenchymal lung disease, $FEF_{25\%-75\%}$ may be reduced and fail to respond to bronchodilators.

The severity of restrictive disease has not been standardized; however, many laboratories classify patients with reduced TLC as mild (TLC less 80%-70%), moderate (TLC 69%-60%), or severe (TLC less than or equal to 60%). These definitions are completely arbitrary because a patient with obstructive lung disease may start with TLC above the upper limit of normal (ie, 120%) and subsequently develop restrictive lung disease while maintaining TLC within the normal range. On the flow-volume loop, patients with restrictive disease have normal-shaped curves with a reduction in the height and width of the curve because both PEF rate and VC depend on the amount of air within the lung prior to performance of expiratory maneuvers (see Figs. e43-3 and e43-4).

⑥ Restrictive lung function is caused by increased elastic recoil of the lung parenchyma (interstitial lung disease), respiratory muscle weakness, mechanical restrictions (chest wall deformities), and/or poor effort. Table e43-5 lists common causes of restrictive lung disease.

TABLE e43-5

Causes of Restrictive Lung Disease

- Interstitial lung diseases
  - Idiopathic pulmonary fibrosis
  - Sarcoidosis
  - Collagen vascular disease
  - Pneumoconiosis
  - Drug-induced lung disease
  - Pulmonary edema
- Infiltrative lung diseases
  - Granulomatosis
  - Tumor
- Pleural diseases
  - Pleural effusion
  - Fibrothorax
  - Pneumothorax
- Chest wall diseases
  - Kyphoscoliosis
  - Ankylosing spondylitis
  - Neuromuscular disease
- Miscellaneous causes
  - Obesity
  - Pregnancy
  - Ascites
  - Paralyzed diaphragm
  - Lung resection

Restrictive lung function from parenchymal lung disease usually can be differentiated from processes causing mechanical restriction as a result of chest bellows malfunction (Table e43-6). Restrictive parenchymal diseases are associated with a reduction in V_A and an increase in lung elastic recoil. All lung volumes, as well as DLCO, are reduced. Compared to patients with restriction secondary to neuromuscular disease, in patients with interstitial lung disease, the RV/TLC (normally less than or equal to 30%) and measurements of maximal inspiratory pressure (normal = −75 cm H_2O [−7.4 kPa] in males, −50 cm H_2O [−4.9 kPa] in females) remain normal. In addition, patients exhibit mild resting hypoxemia that worsens with exercise. Monitoring gas exchange during exercise may be the most sensitive test for detecting the progression of interstitial lung disease; however, this involves obtaining arterial blood during exercise, and DLCO and exercise pulse oximetry are often used in its place.

TABLE e43-6

Patterns of Pulmonary Function

	Obstructive Lung Disease		Restrictive Lung Disease	
	Asthma	**COPD**	**Parenchymal Disease**	**Chest Bellows Disease**
FVC	Nl or I	Nl or I	D	D
FEV_1	D	D	D	D
FEV_1/FVC	<70% (0.70)	<70% (0.70)	≥75%-80% (0.75-0.80)	≥75%-80% (0.75-0.80)
TLC	Nl or I	Nl or I	D	D
RV/TLC	Nl or I	Nl or I	Nl	I
Airway resistance	I	I	N	Nl
DLCO	Nl	D	D	Nl

D, decreased; I, increased; Nl, normal.

Mechanical restriction caused by chest bellows malfunction may result from chest wall or skeletal deformity, loss of neuromuscular function, fibrosis of the pleural space, and abdominal overdistension causing upward displacement of the diaphragm, as well as decreased diaphragm movement. The most common pulmonary function pattern seen in these patients is a decrease in TLC and VC with only a slight decrease in RV. RV is maintained in these diseases because lung compliance remains normal. DLCO is normal or only minimally reduced, and $DLCO/V_A$ (corrected for V_A) is normal. RV/TLC often is increased in patients with restrictive chest bellows disease.

Spirometry in Children

Spirometry was originally focused on the adult population, utilized to diagnose and track the progression of different disease states. Children began evaluation for similar issues including asthma. ⑨ Children can perform most of the pulmonary function tests that adults can, but with modifications. These modifications are important factors that play a significant role in the success of pediatric PFTs.

FEV_1 has been found to contribute to the diagnosis of obstructive lung diseases in adults, but in children, it has been found that they have higher elastic recoil than adults with faster emptying of the lung, which means that the FEV_1 can be relatively insensitive to early lung disease. Some children are able to exhale completely in 1 second.[25] For this reason, as the clinician, this must be taken into consideration when analyzing the data for a diagnosis or treatment plan.

ATS/ERS standards in children do not require a 6-second exhalation for spirometry, but instead, recommend 3 to 5 seconds for children younger than 10 years. If a child fails to blast out for a minimum of 3 seconds but is giving full effort and cooperation, the clinician can override the rejected maneuver. Another common challenge for children is performing the inspiratory maneuver during spirometry. One of the greatest challenges is performing an open-circuit spirometry test where the child inserts the mouthpiece into their post maximal inhalation. Children's coordination is not yet well enough developed to successfully complete spirometry this way, instead, you should instruct the child to insert the mouthpiece into their mouth prior to maximal inhalation with a good seal. An experienced and well-trained clinician working in a PFT lab will have the knowledge and skillset to recognize when a child may or may not have these capabilities and how to modify the maneuver to produce the best results possible. Unlike in adults, you can utilize results that do not meet standards to aid in the diagnosis and treatment plan of a child.

When doing spirometry in children, coaching the child is key to their success. A few things to keep in mind when coaching a child through spirometry are listed as follows:

- Sit down and become eye level with them
- Do not use medical terminology, explain the test in elementary verbiage
- Make it a competition, challenge them to a race.
    - Who can blow out the most candles?
    - Who can blow the fastest and hardest?
- Offer incentives.
    - Candy
    - Stickers
    - Most pediatric PFT clinics will have a treasure chest
- Build trust with them, ask questions to learn about their interest
- Do not test in front of the parents
- Be energized, positive and motivating!

Producing adequate and repeatable pulmonary function tests data in children is, in fact, possible. It requires patience, understanding, dedication, critical thinking, and integration to successfully diagnose and treat a pediatric patient. It requires a clinician who has been trained and certified in performing pulmonary function tests.

ABBREVIATIONS

ACOS	asthma-COPD overlap syndrome
ATS	American Thoracic Society
COPD	chronic obstructive pulmonary disease
DL	diffusing capacity of the lungs
DLCO	diffusing capacity of lung for carbon monoxide
ERS	European Respiratory Society
ERV	expiratory reserve volume
FEF	forced expiratory flow
$FEF_{25\%-75\%}$	forced expiratory flow during 25% to 75% of forced vital capacity
$FEF_{50\%}$	forced expiratory flow at 50% of vital capacity

FEF_{max}	maximum forced expiratory flow
$FEV_{0.5}$	forced expiratory volume at 0.5 second
FEV_1	forced expiratory volume in the first second of expiration
FEV_6	forced expiratory volume in 6 seconds
$FIF_{50\%}$	forced inspiratory flow at 50% of vital capacity
FRC	functional residual capacity
FOT	forced Oscillation Technique
FVC	forced vital capacity
GINA	Global Initiative for Asthma
GLI	Global Lung Initiative
IC	inspiratory capacity
IRV	inspiratory reserve volume
NHANES	National Health and Nutrition Examination Survey
MIP	maximal inspiratory pressure
MEP	maximal expiratory pressure
$P(A–a)O_2$	alveolar–arterial difference in the partial pressure of oxygen
$PaCO_2$	arterial partial pressure of carbon dioxide
PaO_2	arterial partial pressure of oxygen
PC20	provocative concentration needed to cause a 20% fall in FEV_1
PD15	provocative dose 15
PEF	peak expiratory flow
PFT	pulmonary function test
PJP	*Pneumocystis jiroveci* pneumonia
PO_2	partial pressure of oxygen
RV	residual volume
SaO_2	arterial oxygen saturation

SpO_2	oxygen saturation as measured by pulse oximetry
SVC	slow vital capacity
TLC	total lung capacity
V_A	alveolar volume
VC	vital capacity
V_T	tidal volume

SELF-ASSESSMENT QUESTIONS

1. The diagnosis of “obstructive” pattern in pulmonary function testing requires one of the following:
    - A. Positive bronchodilator response
    - B. Increased FEV_1/FVC ratio
    - C. Decreased FEV_1/FVC ratio
    - D. Increased total lung capacity
    - E. Decreased residual volume
2. A positive bronchodilator response is defined as:
    - A. Increase in FEV_1 >500 mL

B. Increase in FEV_1>200 mL

C. Increase in FEV_1>12%

D. Increase in FEV_1 >200 mL and 12%

3. A patient can be described as having “air trapping” on their pulmonary function testing when which of the following finding is present?

A. Increased total lung capacity

B. Increased residual volume

C. Increased DLCO

D. Increased FEV_1/FVC ratio

4. The following are causes of restrictive lung pattern in pulmonary function tests except:

A. Pleural effusion

B. Pulmonary fibrosis

C. Asthma

D. Neuromuscular disease-causing weakness of the respiratory muscles

5. A 64-year-old woman presents to the primary care physician with dyspnea on exertion and chronic cough. She is a current smoker and has been smoking one pack of cigarettes a day for 40 years. Her physician suspects the diagnosis of COPD. What set of pulmonary function test confirms the diagnosis?

Choice	FEV_1	FVC	FEV_1/FVC	TLC	RV	DLCO
A	N	N	Normal	Normal	Normal	Normal
B	N	N	Normal	Normal	Normal	Low
C	L	L	Low	Low	Normal	Normal
D	L	L	Low	High	High	Low

6. All of the following are causes of an isolated diffusion defect except:

A. Asthma

B. Anemia

C. Early interstitial lung disease

D. Pulmonary hypertension

7. A 50-year-old man with a history of prior tobacco use presents to the primary care provider for evaluation of chronic cough and progressive dyspnea. He is found to have bilateral dry crackles on physical examination. His pulmonary function testing reveal an FEV_1 0.5 L (23% predicted),

FVC 0.6 L (25% predicted), and FEV_1/FVC of 79% (0.79). His total lung capacity is 48% predicted and his DLCO is 40% predicted which of the following statement correctly characterizes the observed abnormality?

A. Severe airway obstruction

B. Severe Restriction

C. Normal pulmonary function tests

D. Hyperinflation

8. What is the most likely diagnosis for the patient described above?

A. Pulmonary hypertension

B. Tracheal stenosis

C. COPD

D. Interstitial lung disease

9. Which of the following finding would you expect to see when you evaluate the flow-volume loop obtained during a forced vital capacity maneuver in a patient with a tumor causing a fixed intrathoracic airway obstruction?

A. Flattening of the inspiratory and expiratory limbs of the flow-volume loop

B. Flattening of the inspiratory limb of the flow-volume loop

C. Flattening of the expiratory limb of the flow-volume loop

D. A “scooped-out” appearance to the expiratory limb of the flow-volume loop.

10. One of the following is true regarding the lung volumes and expiratory flows:

A. The volume of air exhaled during normal quiet breathing is the V_T. The maximal volume of air inhaled above V_T is the *expiratory reserve volume*

B. *Vital capacity* (VC) is equal to the sum of IRV, V_T, and TLC

C. Total lung capacity is equal to the sum of ERV, V_T, and RV

11. Which of the following statements is correct regarding the pulmonary functions tests?

A. The spirometry is effort independent

B. Lung volume measurement with plethysmography is more reliable than dilutional methods

C. The gas used to measure the diffusion capacity of the lungs is Nitrogen

D. A bronchoprovocation challenge is positive when the FEV_1 drops by 20% after the administration of albuterol

12. The measurement of MIP (maximal inspiratory pressure) and MEP (maximal expiratory measure) can be useful for the diagnosis and follow-up of:

A. Asthma

B. Pulmonary hypertension

C. Amyotrophic lateral sclerosis

D. Alpha-one antitrypsin deficiency

13. One of the following is true regarding pulmonary function tests in patients with COPD.

A. A positive bronchodilator response excludes the diagnosis.

B. The lung volumes are low.

C. The diffusion capacity is increased.

D. The FEV_1/FVC ratio is <70% (0.70).

14. Which of the following patients is expected to have a significant drop in oxygen saturation during a 6-minute walk test?

A. A 21-year-old female with uncontrolled asthma

B. A 65-year-old male with diffuse alveolar hemorrhage and a DLCO of 110%

C. A 60-year-old male with severe emphysema and a DLCO of 30%

D. A 50-year-old female with tracheal stenosis

15. The following statement is true regarding pulmonary function testing.

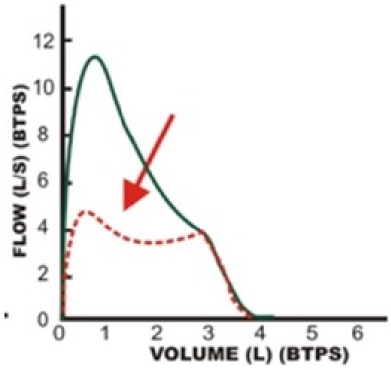
A. PFTs can only be completed in highly specialized centers.

B. Systolic heart failure is a contraindication for PFTs.

C. The normal values are standard and independent of race, height, and gender.

D. Morbidly obese patients can present with a mild restriction pattern with normal diffusion.

16. The following cure is consistent with which of the following commonly seen issues when performing spirometry on your patient?



A. A leak in the system

B. Variable effort

C. Early termination

D. Coughing in the first second

17. You have an 8-year-old pediatric patient who is performing spirometry and blasts out for 2 seconds. This maneuver is considered:

A. Rejected; it does not meet ATS/ERS standards.

B. Acceptable; meets ATS/ERS standards.

C. Children cannot perform spirometry.

D. Should not be rejected, it aids in the diagnosis and treatment of the child; does not meet ATS/ERS standards.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Obstruction is defined as a decreased FEV_1/FVC ratio in spirometry. Both values are affected but the FEV_1 is decreased to a greater extent that makes the ratio low.

2. **D.** A positive bronchodilator response is defined by an increase of 12% and 200 mL after the administration of a β-agonist. Both criteria need to be met.

3. **B.** Air trapping is defined as the inability to fully exhale and diagnosed when the residual volume is increased above 120% normal.

4. **C.** Asthma is characterized by an obstructive pattern on spirometry, all the other pathologies have a restrictive pattern.

5. **D.** The diagnosis of COPD is based on an FEV_1/FVC ratio of <70% (0.70), patients often have increased lung volumes and decreased diffusion capacity.

6. **A.** Patients with asthma have normal and occasionally increased diffusion. All the other options decrease the diffusion capacity.

7. **B.** The patient has decreased FEV_1 and FVC with a normal ratio, the lung volumes are low which confirms the diagnosis of restriction.

8. **D.** The patient most likely has an interstitial lung disease. Classical findings for the alternative diagnoses would include—PAH: diffusion defect; tracheal stenosis: abnormal flow/volume loop; COPD: obstruction pattern on spirometry.

9. **C.** A fixed intrathoracic obstruction, for example, a central airway tumor will cause a flattening of the expiratory limb of the flow volume curve (Fig. e43-5).

10. **A.** Tidal volume is defined as the "normal" volume of air displaced between inhalation and exhalation.

11. **B.** Plethysmography is a more accurate measurement of lung volumes as it accounts for trapped air that cannot be accounted for with nitrogen washout (dilutional methods).

12. **C.** MIP and MEP are used to assess respiratory muscle strength and can be used to assess disease progression in patients with neuromuscular diseases.

13. **D.** Per most recent GOLD guidelines obstruction (in the setting of COPD) is defined as an FEV_1/FVC ratio <70% (0.70) of the predicted value.

14. **C.** Emphysema destroys the alveolar units, therefore decreasing the area of gas exchange. The other scenarios present with normal or even increased diffusion.

15. **D.** Obese patients can have low lung volumes due to the pressure of the abdomen pushing the diaphragm up. Pulmonary function test can be easily achieved in various settings and has few contraindications.

16. **B.** Variable effort. The curve lacks a sharp peak on the initial blast-out and shows no consistency in the expiratory flows.

17. **D.** Should not be rejected, it aids in the diagnosis and treatment of the child and does not meet ATS/ERS standards. Although the produced results do not meet ATS/ERS standards, because this is a pediatric patient, the data can still be utilized to aid in the diagnosis and treatment plan of the child.

Chapter e48: Drug-Induced Pulmonary Diseases

Margaret A. Miklich; Mojdeh Heavner

KEY CONCEPTS

KEY CONCEPTS

① The most common drug-induced pulmonary diseases (DIPDs) are interstitial pneumonitis and pulmonary fibrosis.

② DIPD is a diagnosis of exclusion.

③ The occurrence of DIPD is unpredictable, but there are agent and population-specific risk factors, including extremes of age, the dose of the offending agent, and preexisting lung conditions.

④ Prevention includes avoiding causative agents in high-risk patients.

⑤ Early recognition of DIPD is essential to improving long-term outcomes.

⑥ Management of DIPD commonly involves discontinuation of the causative agent and treatment with corticosteroids.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Lung Disease and Double Lung Transplantation” at Stanford: “Jen Julian’s Story” (link: https://stanfordhealthcare.org/stanford-health-care-now/2012/julian-interstitial-lung-disease.html) from Stanford Health Care. This 5-minute video shares the patient perspective of living with a severe interstitial lung disease ultimately necessitating transplantation. While the etiology of this patient’s chronic hypersensitivity pneumonitis is believed to have been from an inhaled environmental exposure, certain medications can cause a similar condition. The video adds a personal connection to the impact healthcare providers can have on patients with DIILD.

INTRODUCTION

Clinicians should be familiar with drug-induced pulmonary diseases (DIPD) to promptly identify cases and manage complications to minimize potential morbidity and mortality. In the United States, over 2 million adverse drug reactions (ADRs) and 100,000 drug-associated deaths are reported annually. Pulmonary complications may represent the largest proportion of fatalities from ADRs.[1,2] Certain medications and patient-specific situations carry a greater risk for pulmonary ADRs. As an example, up to 10% of patients receiving chemotherapy and up to 40% of patients receiving chemotherapy with bleomycin may develop pulmonary toxicity.[1] The website pneumotox.com and associated Android and iPhone applications list over 1,500 medications reported to cause DIPD, 650 patterns of DIPD, and 10,000 references. This resource functions as a free searchable database for clinicians. The true rate of drug-induced reactions is likely underestimated because there is a challenge in reaching a definitive diagnosis of DIPD, and estimates largely rely on case reports and observational studies.

DIPD may result from direct or indirect drug effects. Direct effects may present as an idiosyncratic reaction or through direct pulmonary toxicity from a drug or its metabolites. DIPD can affect a variety of pulmonary tissues and structures. The clinical presentation and patient symptoms associated with DIPD are often nonspecific. Patients may complain of pleuritic chest pain, dyspnea, cough, wheezing, and fever. Symptoms may be present at rest or during activity. When DIPD affects the vasculature, it often presents with pulmonary hemorrhage or vasculitis, hemoptysis, hematoma, or alveolar hemorrhage. DIPD is a diagnosis of exclusion. It should be considered when a patient has had a known drug exposure and subsequently develops new signs and symptoms consistent with DIPD clinical presentation. The resolution of symptoms after drug withdrawal is particularly informative. Radiographic imaging, including X-rays and CT scans, can help rule out other potential causes of pulmonary disease and establish the diagnosis of DIPD.[3]

Table e48-1 summarizes DIPD diagnostic considerations and general management strategies.

TABLE e48-1

Summary of Drug-Induced Pulmonary Disease – Presentation, Diagnosis, Causative Agents, and Management

Disease	Presentation	Key Diagnostic Components	Causative Agents	Management
Reactions involving the interstitium				
Interstitial pneumonitis and fibrosis[1,18,53]	Can be acute or chronic Dyspnea, cough, Clubbing, crackles	History of drug exposure Bilateral localized or diffuse opacities and reduced lung volumes on CXR “Honeycombing” on chest CT Elevated ESR with amiodarone Restrictive/normal PFTs	Amiodarone, bleomycin, gemcitabine, carmustine, cyclophosphamide, taxanes, EGFR inhibitors, dasatinib, mTORi, busulfan, sulfasalazine, methotrexate, leflunomide, phenytoin, nitrofurantoin, daptomycin	Drug discontinuation, dose reduction or interruption Corticosteroids Supplemental oxygen
Organizing pneumonia[22]	Nonproductive cough, shortness of breath, bilateral crackles Less commonly, fever	History of drug exposure Bilateral patchy infiltrates on CXR Rarely, eosinophilia present	Amiodarone, bleomycin, minocycline, nitrofurantoin, gold, sulfasalazine, interferon alpha, carbamazepine, L-tryptophan, cocaine	Drug discontinuation Corticosteroids Supplemental oxygen
Eosinophilic pneumonia (Bartel 2018)	Can be acute or chronic Dry cough, dyspnea, chest pain, fever	History of drug exposure Bilateral reticular ground-glass opacities on chest CT Acute: elevated	Daptomycin, mesalamine, sulfasalazine, minocycline	Drug discontinuation Corticosteroids Omalizumab Supplemental oxygen Acute:

		peripheral neutrophils with high BAL eosinophils Chronic: elevated peripheral eosinophils, elevated IgE, CRP, ESR			mechanical ventilation common
Hypersensitivity pneumonitis[15,36]	Usually, immediate Urticaria, angioedema, rhinitis, conjunctivitis, dyspnea, and bronchospasm	History of drug exposure Based on presentation	NSAIDS (dose-dependent), methotrexate, nitrofurantoin		Drug discontinuation Corticosteroids Antihistamines Supplemental oxygen
Noncardiac pulmonary edema[35]	Dyspnea, chest discomfort, tachypnea, hypoxemia	History of drug exposure Interstitial and alveolar infiltrates Laboratory values and PFTs not helpful	Cytarabine, gemcitabine, immune globulins, interleukin, methotrexate, mitomycin muronomab-CD3, pentostatin, tretinoin, tricyclic antidepressants, aspirin (dose-dependent), methadone, morphine, oxytocin, protamine, heroin, cocaine, cytarabine, infliximab, GM-CSF, vinca alkaloids, amiodarone, nitrofurantoin, talc		Drug discontinuation Diuretics Supplemental oxygen Mechanical ventilation ? Role corticosteroids
Diffuse alveolar damage[54]	Typically acute, can be subacute Hemoptysis, cough, dyspnea, acute respiratory failure	History of drug exposure New or unexplained infiltrates on CXR Dropping hematocrit Hemorrhagic BAL	Chemotherapy, all-trans-retinoic acid, propylthiouracil, penicillin, sulfasalazine, hydralazine, leukotriene antagonists, mitomycin, amiodarone, nitrofurantoin, crack cocaine, thrombolytics, anticoagulants, antiplatelet agents, dextran 70		Drug discontinuation Reversal of coagulation Corticosteroids for chemotherapy-induced Supplemental oxygen
Reactions involving the pleura					
Nonlupus-related pleural effusion[29]	Pleuritic chest pain, pleural effusions	History of drug exposure Pleural fluid eosinophilia (nonspecific)	Sclerotherapy agents (most common), amiodarone, minoxidil, methysergide, bromocriptine, bleomycin, mitomycin, procarbazine, methotrexate, cyclophosphamide, dasatinib		Drug discontinuation Corticosteroids Supplemental oxygen

		Elevated peripheral eosinophils		
Lupus-related pleural effusion[29]	Pleuritic chest pain, pleural effusions	History of drug exposure Similar to idiopathic lupus Pleural fluid: exudative, ANA higher than serum values, lupus erythematosus cells may be present	Procainamide (most common), hydralazine, chlorpromazine, isoniazid, D-penicillamine, methyldopa, quinidine	Drug discontinuation Supplemental oxygen
Reactions without direct toxic effect to the lung tissue				
Bronchospasm[10]	Wheezing	History of drug exposure Based on presentation	Acetaminophen, aspirin, NSAIDs, beta-blockers, iodinated radiocontrast dye	Drug discontinuation Corticosteroids Supplemental oxygen
Cough (Shim 2019)	Can occur within hours to months Persistent dry cough, “tickle” in throat	History of drug exposure Based on presentation	ACE-inhibitors, calcium channel blockers, fentanyl, latanoprost ophthalmic	Drug discontinuation
Pulmonary arterial hypertension[24,39]	Dyspnea	History of drug exposure mPAP ≥25 mmHg at rest during RHC	Anorectic agents, amphetamines, dasatinib, selective serotonin inhibitors (risk to newborn if mother taking)	Drug discontinuation Pulmonary vasodilators
Thromboembolic disorders[39,42]	Dyspnea	History of drug exposure Pulmonary embolism on chest CT	Bleomycin, cyclophosphamide, alkylating/alkylating-like agents, mitomycin, high dose combined oral contraception, immune checkpoint inhibitors	Drug discontinuation Anticoagulation Thrombolysis Supplemental oxygen
Apnea[15,19] (Boiter 2020)	Hypoventilation	History of drug exposure Based on presentation	Opioids, neuromuscular blockers	Dose reduction or discontinuation of drug

				Naloxone (for opioids)
Chest wall rigidity[50]	Decreased compliance of chest wall, respiratory muscles, or laryngeal structures	History of drug exposure Based on presentation	Synthetic opioids (fentanyl, remifentanyl, methadone), also morphine	Dose reduction or discontinuation of drug

CXR, chest X-ray; CT, computerized tomography scan; ESR, erythrocyte sedimentation rate; PFTs, pulmonary function tests; EGFR, epidermal growth factor receptor; NSAIDS, nonsteroidal anti-inflammatory drugs; mTORi, mechanistic target of rapamycin inhibitors; CRP, c-reactive protein; GM-CSF, granulocyte-macrophage colony-stimulating factor; BAL, bronchoalveolar lavage; ANA, antinuclear antibodies; mPAP, mean pulmonary arterial pressure; RHC, right heart catheterization.

The clinical spectrum of DIPD is heterogeneous; narrowing down the affected region of the lung can assist with identifying a distinct diagnosis and subsequent management approach. DIPD most frequently impacts the pulmonary parenchyma, but can affect the pleura, airways, pulmonary vasculature, mediastinum, and neuromuscular respiratory system (see Fig. e48-1). Notable manifestations can include interstitial pneumonitis, fibrosis, pleural effusions, or drug-induced lupus.[3]

FIGURE e48-1

Depiction of lung anatomy involved in drug-induced reactions. The trachea and bronchi serve to transport air into the lungs. Smaller bronchioles may carry air or lead to gas exchange in alveoli. Lung parenchyma, sometimes referred to as lung interstitium, is involved in gas exchange and includes alveoli, interstitium, and capillaries. Lung pleurae are lubricated membranes that protect the lungs and aid in expansion and contraction. The inner membrane (visceral pleura) lines the lungs, the outer membrane (parietal pleura) lines the chest wall, and the area in between is called the pleural space. The main muscle of breathing is the diaphragm; intercostal muscles may also contribute. The brainstem along with nerves and chemoreceptors (not shown) control breathing. Pulmonary vasculature includes veins, arteries, and capillaries which function to carry unoxygenated blood into the lungs and oxygenated blood out of the lungs. The mediastinum is the cavity containing extrapulmonary structures including the heart.

DRUG-INDUCED REACTIONS

Reactions Involving the Interstitium

When considering ADRs with direct toxic effects on the lungs, drug-induced interstitial lung disease (DIILD) is the most common. Drugs are the primary cause of between 2.6% and 6.4% of interstitial lung disease (ILD).[20] Reactions involving the interstitium include pulmonary fibrosis, pneumonitis, organizing pneumonia, eosinophilic pneumonia, hypersensitivity pneumonia, noncardiac pulmonary edema, and diffuse alveolar damage/diffuse alveolar hemorrhage (DAD/DAH). A causative agent can precipitate more than one type of interstitial reaction.

Interstitial Pneumonitis and Fibrosis

Incidence

The most common reactions involving the interstitium are interstitial pneumonitis and fibrosis. Agent-specific incidence of pneumonitis and/or fibrosis is described in "Causative Agents" section.

Presentation and Diagnosis

DIILDs are a heterogeneous set of disorders that may present acutely, subacutely, or chronically. Multiple methods of nomenclature and classification have been proposed.[21,22] Drug-induced interstitial pneumonitides commonly have histopathologic features of usual interstitial pneumonia or nonspecific interstitial pneumonia. Findings often overlap with those of drug-induced pulmonary fibrosis or idiopathic pulmonary fibrosis (IPF). Common acute signs and symptoms of interstitial pneumonitis include nonproductive cough and sudden onset dyspnea over a period of hours. Other manifestations of the acute form may include fever, rash, or eosinophilia. On the other hand, more chronic forms of the disease present as progressive breathlessness, which may lead to reduced capacity for physical activity.[1,5] During lung auscultation, most patients with interstitial pneumonitis or fibrosis will demonstrate crackles upon expiration. Digital clubbing may be detected in up to half of patients. Though not useful in making an initial diagnosis, once the disease progresses to fibrosis, cyanosis or signs of pulmonary hypertension may emerge.[1,5]

Imaging can be helpful in confirming the presence of ILD when considered in the context of other clinical features but is not useful for distinguishing the etiology of the disease. Initially, a chest radiograph may be used to exclude differential diagnoses such as infectious processes or pulmonary edema. If the disease progresses to fibrosis, radiography may show abnormalities such as decreased lung volumes or bilateral diffuse ground-glass opacities.[5] High-resolution computed tomography (HRCT) is the most sensitive imaging technique available for the detection of ILD, with up to 100% of patients showing abnormalities.[1] In an acute presentation, HRCT may reveal diffuse ground-glass opacity. In fibrosis, the hallmark pattern found on HRCT is “honeycombing,” which results from the destruction of the alveolar structure, causing irregularly shaped enlarged airspaces.

Other non-imaging tests may be completed during the diagnostic workup. Pulmonary function tests (PFTs) may not be possible to obtain in patients with more progressive disease. If measured, spirometry can show a normal pattern initially or progress to a restrictive pattern. Restrictive lung disease is marked by a reduced total lung capacity and forced vital capacity on spirometry. Interstitial pneumonitis and particularly fibrosis often leads to impaired gas exchange in the pulmonary parenchyma, so the carbon monoxide diffusing capacity may also be reduced. Conventionally, arterial oxygen saturation may be easier to measure. Patients may have normal or low saturation at rest and commonly become hypoxemic upon exertion.[1,5] Laboratory tests are generally not helpful when investigating a diagnosis of DIILD though increased eosinophils or erythrocyte sedimentation rate (ESR) may be present in specific instances.[5] Bronchoscopy with bronchoalveolar lavage (BAL) can assist in ruling out malignancy or infection and can be relevant to DIILD diagnosis when used in conjunction with other presenting features. Cell differentials from BAL may point the clinician to a specific type of DIILD. For example, nonspecific interstitial pneumonia tends to have mixed cellularity on BAL and pulmonary fibrosis may show a neutrophilic pattern.[1] There is limited evidence for routine use of open lung biopsies in the investigation of DIILD. This procedure may be used to rule out other etiologies of disease or add valuable data when the diagnosis is uncertain but may be unsafe for patients with advanced disease.

Mechanisms of Toxicity

There are several proposed mechanisms for the pathogenesis of DIILD. While reliable evidence is lacking, the underlying pathophysiology shares a common pathway with IPF. Pathogenesis may differ across agents. Leading theories include oxidative stress and direct cellular injury, as depicted in Fig. e48-2.[5,23] Figure e48-3A visually depicts a normal alveolus and Fig. e48-3B depicts the parenchymal changes seen in fibrosis.

FIGURE e48-2

Schematic of proposed risk factors and mechanisms for the development of lung fibrosis. Risk factors may include genetic susceptibility, concomitant drugs, age, drug exposure, or preexisting lung disease. A direct toxic effect of oxidative stress causes damage to alveolar epithelial and endothelial cells. The damage leads to increased permeability, vascular leak, the release of inflammatory cells and mediators, and platelet activation with clot formation. In pneumonitis, inflammation may be temporary. In fibrosis, the damage is followed by the recruitment of fibroblasts, abnormal cellular repair, and apoptosis. Ultimately, there is excess deposition of extracellular matrix leading to remodeling, honeycombing, and fibrosis.

Causative Agents

Many medications have been implicated in interstitial pneumonitis and pulmonary fibrosis. As new drug molecules are developed, approved, and used in clinical practice, the list of causative agents will continue to grow. Conversely, the incidence of DIILD may decline for agents that are no longer favored in clinical practice. Most agents fall within one of several classes, including antimicrobial, antineoplastic, antirheumatic, and cardiovascular. While not exhaustive, the agent-specific mechanisms, presentation, incidence, and mortality rates are described for the most common causative agents.

Antimicrobial

Nitrofurantoin is an antibiotic often used to treat or prevent cystitis. This agent causes DIPD via oxidant/antioxidant imbalance.[5] The most commonly presenting reaction is acute eosinophilic pneumonia, which is described in the "Eosinophilic Pneumonia" section of this chapter. However, long-term use of nitrofurantoin can cause chronic interstitial pneumonia presenting as pulmonary fibrosis, which has been reported from 8 months to 16 years of treatment.[24] One registry showed that less than 10% of nitrofurantoin-associated DIPD present chronically but the mortality rate for this form was 8%.[25]

Antineoplastic

Bleomycin is an antibiotic and neoplastic agent used to treat several tumor types. The proposed mechanism of bleomycin-induced pneumonitis (BIP) is the induction of cytokines, inflammatory cells, and free oxygen radicals.[26] BIP is a well-known and common ADR of bleomycin therapy. It typically presents weeks to months after treatment initiation and may progress to fibrosis. The estimated incidence of BIP is 6.8% to 21%, with a reported mortality of up to 48%.[20]

Busulfan is an alkylating agent commonly used in conditioning regimens prior to hematopoietic stem cell transplantation. Pulmonary fibrosis due to busulfan, commonly referred to as "Busulfan Lung," is due to direct alveolar injury. The condition presents an average of 4 years after monotherapy use and months after high dose use. Incidence has been reported to be approximately 6%.[27]

Carmustine is a nitrosourea used to treat certain lymphomas, myelomas, and brain tumors. Acutely presenting pneumonitis may occur months to years after initiating therapy; chronic pulmonary fibrosis may present years after therapy. Upper lung lobes tend to be most impacted. The estimated incidence of these reactions is 1.5% to 20%.[27]

Cyclophosphamide is an alkylating agent typically combined with other antineoplastic agents to treat malignancies. It is also used to treat certain inflammatory and autoimmune disorders. Early-onset pneumonitis generally presents within months of initiation and typically responds to glucocorticoids, whereas late-onset pneumonitis presents within months to years and is often progressive and permanent.[27] The cyclophosphamide-induced lung reactions are rare, with an estimated incidence of 1%.[5]

Epidermal growth factor receptor inhibitors (EGFRIs) such as erlotinib, gefitinib, mobocertinib, and osimertinib are small-molecule tyrosine kinase inhibitors used to treat non-small cell lung cancer. DIILD, which could present as pneumonitis, fibrosis, or DAD, most often develops within one month of treatment initiation. The incidence of DIILD with erlotinib and gefitinib is reported to be between 1.2% and 1.6% with mortality of 22.8%.[20] The incidence of DIILD with mobocertinib and osimertinib is slightly higher at 3.3% to 4.3% though the mortality rate was significantly lower at 0.5% to 1.2%.[28,29] Monoclonal antibody EGFRIs such as cetuximab and panitumumab are primarily used to treat colorectal cancers. According to a postmarketing study in Japan, DIILD associated with these monoclonal antibodies has an incidence of around 1% and a mortality rate of up to 50%. The median onset of DIILD was reported to be about 3 to 4 months after therapy initiation.[20]

Immune checkpoint inhibitors (ICPis) target programmed cell death receptor 1 (PD-1) (eg, nivolumab, pembrolizumab), programmed cell death ligand 1 (PD-L1) (eg, avelumab, durvalumab), or cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) (eg, ipilimumab) and are used to treat a wide array of malignancies. Pneumonitis occurred in less than 1% of trial participants receiving the anti-CTLA-4 drug ipilimumab whereas the incidence of this reaction in patients treated with anti-PD-1 or anti-PD-L1 therapy ranged from 0% to 10%. The median time to onset is reported to be about 3 months, though use of ICPis in combination therapy may trigger earlier onset.[30]

Gemcitabine is a pyrimidine analog used alone or in combination with other agents to treat malignancies, including pancreatic, breast, ovarian, and non-small cell lung cancers. The mechanism of toxicity is from endothelial dysfunction after cytokine release. Gemcitabine is also a radiosensitizer. The onset of symptoms occurs an average of about two months after initiation of therapy. The incidence of DIILD was reported to be 1.1% to 1.9% in a retrospective study in Japan, but other studies found an incidence of up to 20% when used as part of a combination regimen. Mortality is generally low but may reach up to 22% in patients requiring hospitalization.[20,31]

Mechanistic target of rapamycin inhibitors (mTORis) such as everolimus, sirolimus, and temisirolimus are used as rejection prophylaxis is solid organ transplantation as well as to treat certain tumors. The pathogenesis of mTORi-induced pneumonitis is hypothesized to be due to DAD from an autoimmune response or delayed hypersensitivity reaction. In phase II and III trials of patients treated with an mTORi for breast cancer, the incidence of pneumonitis ranged from <0.5% to 42% and grade 3 or 4 pneumonitis ranged from 0% to 9%. In one trial, the median time to onset was 51 days in patients treated with daily everolimus and 104 days in patients treated with weekly everolimus. The patients treated with daily everolimus were about twice as likely to develop mTORi-associated pneumonitis than those treated with weekly regimens. Most cases resolve with discontinuation of the mTORi and/or treatment with corticosteroids.[4]

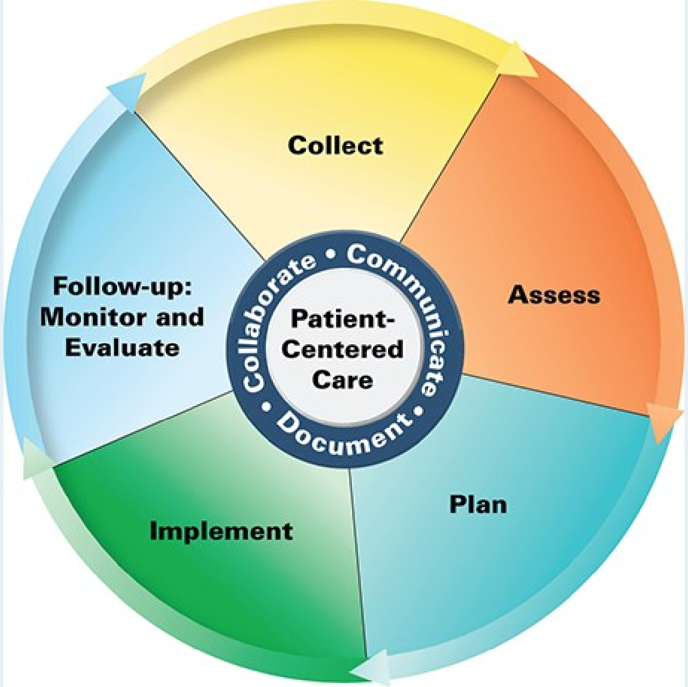
Taxanes such as paclitaxel, nanoparticle albumin-bound paclitaxel, and docetaxel are antimicrotubular agents used to treat a variety of malignancies. They cause interstitial pneumonia via delayed hypersensitivity mechanism or direct toxic effect but are also reported to cause organizing pneumonia or DAD.[32,33] In one case series of patients with non-small cell lung cancer treated with docetaxel, the incidence of interstitial pneumonitis was 4.6%.[33] Onset was acute or subacute in nature and most frequently occurred during cycle 2 of therapy with a median onset of 18 days after the last administration. The incidence of paclitaxel-induced ILD has been reported to be from 0.7% to 12%.[34]

Antirheumatic

Leflunomide is used in the treatment of rheumatoid arthritis and exhibits antiproliferative, anti-inflammatory, and immune-modulating properties. In a Japanese study, the incidence of leflunomide-associated ILD reportedly declined from 1.46% to 0.63% after a risk advisory was issued.[20]

Methotrexate is a folate antimetabolite with antineoplastic, antiproliferative, anti-inflammatory and immune-modulating properties used to treat certain malignancies, psoriasis and connective tissue diseases such as rheumatoid arthritis. The mechanism of DIILD remains unclear but is proposed to be hypersensitivity or direct toxic effect.[5,35] The incidence of methotrexate-induced ILD is reported to range from 0.06% to 15% with mortality ranging from 10% to 33%. The onset of the reaction can vary from days to years.[20] For patients treated with low-dose methotrexate for rheumatoid arthritis, a published literature review found the incidence of methotrexate pneumonitis to be 0.43%.[36] Interestingly, though folic acid may be used to mitigate some methotrexate ADRs, it does not reduce the risk of pneumonitis.[37]

Patient Care Process: Amiodarone-Induced Interstitial Pulmonary Fibrosis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex)
- Patient medical history (eg, preexisting lung disease, radiation)
- Social history (eg, smoking)

- Current medications (eg, amiodarone duration of therapy and daily dose, interacting medications)
- Objective data
    - Vitals (eg, pulse oximetry)
    - Physical exam (eg, lung auscultation, inspection of extremities)
    - Imaging (eg, chest radiograph, HRCT)
    - PFTs (eg, spirometry, diffusing capacity of carbon dioxide [DLCO])

Assess

- Likelihood of drug-induced adverse reaction
    - Clinical presentation consistent with pulmonary fibrosis
    - Presence of risk factors for amiodarone-induced pulmonary fibrosis (eg, advanced age, daily dose > 400 mg, long-term use, preexisting lung conditions)
    - Absence of alternative cause of pulmonary fibrosis
    - Improvement following discontinuation of amiodarone
- Need for alternative antiarrhythmic therapy or implantation of an automatic defibrillator

Plan*

- Discontinue amiodarone
- Establish alternate antiarrhythmic therapy
- Initiate corticosteroids at a dose of 0.5 to 1 mg/kg/day for 6 to 12 months and ensure the dose is tapered gradually upon completion of therapy
- Patient education (eg, the purpose of treatment, corticosteroid-specific information)
- Self-monitoring for improvement in shortness of breath and exercise tolerance
- Referrals to other providers when appropriate (eg, pulmonology, transplant)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, spirometry, DLCO, HRCT, ADR assessment, adherence assessment)

Follow-up: Monitor and Evaluate

- Resolution of symptoms (eg, shortness of breath, improved exercise tolerance)
- Improvement of objective measures (eg, pulse oximetry, spirometry, DLCO, HRCT)
- Presence of adverse effects of corticosteroids (eg, hyperglycemia, hypertension, gastrointestinal upset, weight gain, edema, mood changes, decreased bone density, cataracts, Cushing's Syndrome)

- Patient’s adherence to the treatment plan

[*] *Collaborate with patient, caregivers, and other healthcare professionals*

Cardiovascular

Amiodarone is a class III antiarrhythmic agent used to treat atrial and ventricular arrhythmias. It exerts an adverse effect via phospholipidosis, or excessive accumulation of lipids and drug, in the lung as well as through a direct toxic effect.[38] The most commonly presenting reaction is a subacute or chronic interstitial disease occurring months after the initiation of the agent. Amiodarone-associated ILD occurs at a rate of 1.2% to 8.8%, with a reported mortality of 3% to 37%.[20]

Risk Factors

Multiple risk factors for DIILD have been identified. However, the occurrence of DIILD remains unpredictable, and risk factors vary across patient populations and inciting agents.[5] Though not applicable to all situations, some risk factors may include age extremes, concomitant use of radiation, oxygen, or other inciting medications, the dose of the causative agent, presence of underlying lung conditions and tobacco smoking.

Advanced age is a well-recognized risk for DIILD in certain agents (eg, amiodarone, bleomycin, EGFRIs, gemcitabine, methotrexate, and nitrofurantoin). Impaired renal clearance and oxidant/antioxidant imbalance in patients of advanced age contribute to this effect. On the other hand, the risk of DIILD with carmustine is highest in patients under 7 years of age. Extremes of age do not seem to be a risk factor for disease with other agents, such as mTORis.[5]

Thoracic and total body radiation cause radiation pneumonitis and concomitant or sequential use of certain chemotherapies (eg, bleomycin, cyclophosphamide, gemcitabine, taxanes) may compound risk.[39] Both radiation and chemotherapy can exert direct toxic effects on the lungs and the generation of free radicals. Exposure to high oxygen concentrations can also increase the formation of reactive oxygen species. Theoretically, concomitant oxygen supplementation and bleomycin use can raise the chance of DIILD. While data in animals identify high concentration oxygen as a risk factor, high-quality evidence in humans is lacking.[26]

Cumulative drug exposure increases the likelihood of DIILD with amiodarone, bleomycin, and carmustine. In amiodarone use, both maintenance daily doses greater than 400 mg and cumulative dose are well-established risk factors for DIILD.[40] Increased risk of toxicity is seen with cumulative doses greater than 300 units of bleomycin and 1,400 mg/m^2 of carmustine.[41,42]

The presence of preexisting lung diseases including IPF, chronic obstructive pulmonary disease, and asbestos-induced disease, are recognized risk factors for DIILD.[20] Genetic susceptibility (eg, altered enzyme activity, presence of variant alleles) can impact the likelihood of DIILD.[43] Another predisposing factor may be tobacco smoking, specifically with the use of EGFRIs, gemcitabine, and methotrexate.[20]

Prevention

Two general DIILD prevention strategies exist: avoid causative agents in high-risk patients and limit exposure in patients who must receive treatment with causative agents.[5] Risk factors are agent- and patient-specific and are detailed in the “Risk Factors” section. There is limited guidance for specific DIILD prevention strategies. For example, the National Comprehensive Cancer Network (NCCN) Guideline for Testicular Cancer recommends avoiding bleomycin-containing regimens for certain seminomas in patients who are over 50 years of age, are at increased risk for pulmonary complications, or have underlying lung disease.[44] There are also recommendations related to the use of oxygen in the perioperative period.[45]

Monitoring, Recognition, and Assessment

Early recognition of DIILD is essential but inherently difficult as DIILD is a diagnosis of exclusion. Monitoring protocols for the identification of DIILD have not been well established and are often clinician-dependent. It is good practice to obtain baseline spirometry, DLCO, and chest radiograph with the use of high-risk agents. The patient should be monitored for symptoms at each follow-up. Spirometry and DLCO should be performed frequently, though a decrease in these indices may not occur until more advanced disease is established. A chest radiograph should also be performed at frequent intervals. The frequency of monitoring typically ranges from every 2 weeks to every 4 months, depending on the patient, agent, and clinician-specific factors.[5] Specific monitoring guidelines exist for several causative agents, including bleomycin and amiodarone. When using amiodarone, baseline monitoring of chest radiograph and PFTs including DLCO should be conducted. The chest radiograph along with signs and symptoms should be monitored every 3 to 6 months or if clinically warranted.[46] When using bleomycin, a chest radiograph should be monitored every 1 to 2 weeks, and DLCO should be performed monthly. A decline in DLCO of 30% to 35% from baseline is clinically relevant and warrants intervention.[45]

For high-risk drugs, clinicians should educate patients on self-monitoring of symptoms and consider frequent follow-up to monitor symptoms, PFTs, and imaging. Acutely presenting disease may be more easily identifiable than chronic forms. Careful consideration of patient history, risk factors, and drug exposure must be made. Table e48-2 summarizes diagnostic criteria to consider. The Naranjo Adverse Drug Reaction Probability Scale outlines similar criteria broadly used to identify adverse drug effects.[47]

TABLE e48-2

Diagnostic Criteria for the Presence of Drug-Induced Pulmonary Diseases (DIPD)

History
Known or suspected exposure to a drug known to cause DILD
Current
Clinical and histopathological findings correlate with previous reports of DILD
Other causes of clinical and histopathological findings can be ruled out
Future
Clinical manifestations improve after withdrawal of the drug
Clinical manifestations recur after rechallenge

Data from References 21,48.

The severity of cancer therapy-related ADRs is clearly classified in the Common Terminology Criteria for Adverse Events (CTCAE) document published by the National Cancer Institute.[49] The document is organized by organ system class and includes severity grades 1 through 5 for each ADR. For example, the ADR “pneumonitis” is categorized under “respiratory, thoracic, and mediastinal disorders.” Drug information databases typically use grades to provide recommendations on management. Conversely, the assessment of the severity and predicted mortality from non-cancer therapy DIILD’s have not been well described. The American Thoracic Society/European Respiratory Society issued an update on the classification of idiopathic interstitial pneumonias, but this does not extend to drug-induced causes.[22] Predictive mortality models that exist for IPF and idiopathic interstitial pneumonias have been applied to other forms of the disease, but not specifically to DIILD. The ILD-GAP Index is one such model which incorporates factors like gender, age, and physiology (ie, % predicted FVC and % predicted DLCO) to determine the probability of survival.[50] The intention behind such tools is to provide information to patients, set goals, inform the need for referrals, and determine prognosis.

Management and Treatment

Treatment of DIILD often involves withdrawal of the offending agent, may include corticosteroids or supportive measures, and in extreme cases may require lung transplantation. Early detection of disease and discontinuation of the suspected causative agent is essential.

Corticosteroids are commonly initiated in clinical practice, but high-quality evidence to support the dose, duration, or efficacy of this approach is often lacking. Studies assessing the impact of corticosteroids have been summarized previously, but lack of randomization, incomplete information on dosing or duration, and heterogeneity of the population limit conclusions.[20] Despite weak evidence, corticosteroid dosing recommendations exist for the treatment of DIILD associated with some agents such as ICPis, mTORis, bleomycin, carmustine, and amiodarone.[4,5,30,38,51,52] The NCCN Guidelines for the Management of immunotherapy-related toxicities recommend that moderate (grade 2) pneumonitis be managed with prednisone or methylprednisolone 1 to 2 mg/kg/day until improvement and taper over 4 to 6 weeks. If there is no improvement in 48 to 72 hours or if severe (grades 3-4) pneumonitis is present, give methylprednisolone 1 to 2 mg/kg/day and taper over at least 6 weeks. If there is no improvement, infliximab, intravenous immune globuline, or mycophenolate mofetil can be considered.[52] For DIILD associated with mTORis, a dose reduction or interruption is suggested for grade 2, dose interruption is suggested for grade 3, and permanent discontinuation is suggested for grade 4. Corticosteroids at an equivalent oral prednisone dose of 0.75 to 1 mg/kg are suggested in grades 2 to 4 until pneumonitis improves to grade 1.[4] For DIILD associated with bleomycin, prednisone 0.75 mg/kg/day for a minimum of 4 to 6 weeks followed by a taper has been suggested.[5] For DIILD associated with carmustine, an initial regimen of prednisone 60 mg by mouth twice daily followed by 30 mg by mouth daily and tapered by 5 to 10 mg weekly until discontinuation showed success in breast cancer patients.[51] For DIILD associated with amiodarone, treatment with prednisone 0.5 to 1 mg/kg/day has been suggested. Given the long half-life of amiodarone, it is imperative to continue corticosteroids for several months and often up to 1 year. Cases of relapse have been described in corticosteroid treatment duration under 6 months.[38]

In addition to discontinuing the causative agent and initiating corticosteroids, supportive measures may be required. Patients with hypoxemia may be treated with supplemental oxygen therapy.[1] Mechanical ventilatory support may be needed in acutely severe cases. A referral for lung transplantation may be considered in some patients who have not shown improvement with other measures.[5]

Monitoring

Once the presence of DIILD has been identified and management has commenced, monitoring for disease improvement should occur. A favorable response to treatment of cancer therapy-associated ILD is indicated by improvement (downgrading) of the CTCAE grade.[49] Criteria defining a favorable response to treatment of non-cancer-associated ILD is lacking, but such criteria have been described in the treatment of IPF.[53] Positive response in IPF consists of improvement in symptoms, imaging, and physiologic parameters such as the increase in total lung capacity or vital capacity by ≥ 10% or 200 mL, improvement in DLCO by ≥ 15% or 3 mL/min/mmHg, or normalization or improvement of oxygen saturation by 4%. The goal of management should be to resolve symptoms and prevent progression to fibrosis. Time course to a resolution of acutely presenting interstitial pneumonitis may be days to weeks. Fibrosing disease may take months to improve or may be permanent.[5]

If patients were managed with corticosteroids or other treatments, ADRs should be monitored. For corticosteroids, this may include hyperglycemia, hypertension, gastrointestinal upset, weight gain, edema, mood changes, decreased bone density, and cataracts.

Organizing Pneumonia

Organizing pneumonia, otherwise known as bronchiolitis obliterans organizing pneumonia (BOOP) results from an inflammatory response localized in the lung parenchyma. Figure e48-3A visually depicts a normal alveolus and Fig. e48-3C depicts the parenchymal changes seen in organizing pneumonia.

Patients with BOOP can present with nonproductive cough, dyspnea, and bilateral crackles, with occasional fever and rash, and rarely, eosinophilia. Radiographic imaging of the lung often shows bilateral, patchy infiltrates.

Causative agents are typically antimicrobials (eg, minocycline, nitrofurantoin), chemotherapeutic agents (eg, bleomycin), cardiac agents (eg, amiodarone), anti-inflammatory agents (eg, gold, sulfasalazine), and other miscellaneous agents such as interferon-alpha, carbamazepine, L-tryptophan, and cocaine.[6]

BOOP-related interstitial inflammation is generally reversed by discontinuation of the offending agent or treatment with corticosteroids.

Eosinophilic Pneumonia

Pulmonary infiltrates with eosinophilic pneumonia involve infiltration of the pulmonary parenchyma/interstitium with eosinophils.[7] Figure e48-3A visually depicts a normal alveolus and Fig. e48-3D depicts the parenchymal changes seen in eosinophilic pneumonia.

It can be a primary idiopathic process or secondary to a variety of etiologies but most commonly drug- or toxin-mediated. A potential drug-related mechanism includes eosinophil-specific chemoattractants such as eotaxin, T-cell-expressed chemokines, or IL-5 release from T2 lymphocytes. Other proposed mechanisms are through 5HT2A (in response to antipsychotics or antiepileptic agents) or oxidant injury (in response to daptomycin or nitrofurantoin).[7]

Eosinophilic pneumonia symptoms can include dry cough, dyspnea, chest pain, and fever. BAL typically shows >25% eosinophils as a proportion of all white blood cells present. Lung biopsy for diagnosis is not typically recommended. On imaging, eosinophilic pneumonia involves bilateral reticular ground-glass opacities that expand with disease progression. It is further classified based on chronicity, and questions have been raised about whether acute and chronic eosinophilic pneumonia should actually be considered two entirely separate entities. The disease is classified as acute eosinophilic pneumonia (AEP) if symptoms have been presented shorter than one month (typically less than one week). The chief contrast between AEP and chronic eosinophilic pneumonia (CEP) is that AEP is usually fulminant, and patients have severe hypoxemia, with more than half requiring mechanical ventilation. AEP includes bilateral peripheral or pleural-based nonsegmental consolidations, and ground-glass opacities are less commonly seen as compared with chronic disease. AEP often presents with a peripheral blood neutrophilic leukocytosis without an elevation in the eosinophilic fraction, although there are conflicting data on this observation. In contrast, BAL fluid in acute disease is almost always >25% and frequently reported as >40% eosinophilic fraction. In comparison, CEP is diagnosed 5 months from the onset of symptoms. Patients with CEP commonly present with a productive cough (42%), fever (67%), and dyspnea (80%), but they also have B-type symptoms, including weight loss (60%) and night sweats (47%). Peripheral blood eosinophilia is commonly present with CEP (eosinophil count > 1,000 cells/μL [1.0 ~10^9/L]). Total immunoglobulin E (IgE) levels are also high in half of these patients, along with elevated markers of chronic inflammation such as thrombocytosis, c-reactive protein, or ESR.[7]

Causative agents implicated in secondary eosinophilic pneumonia include antibiotics such as daptomycin, nitrofurantoin, and minocycline, and anti-inflammatory agents such as mesalamine and sulfasalazine. All drug classes have been implicated, but these classes carry a higher risk.[5,7,35]

Eosinophilic pneumonia is treated based on the severity of symptoms. As previously mentioned, patients with severe hypoxemia in AEP will require mechanical ventilation. AEP is commonly (82%) treated with steroids, but the recurrence rate with just discontinuing the offending agent is only 3.7%, and there is no difference in the recurrence rate between AEP treated with steroids versus no steroids. CEP is also often treated with steroids but not as commonly (65%), and the recurrence rate with just discontinuing the offending agent is 3.3%. Notably, patients with CEP treated with steroids have a higher rate of recurrence (6.5%). The optimal duration of steroids, when used, is unknown, but clinicians commonly provide a slow taper over 2 to 3 months. A steroid-sparing regimen with omalizumab can be considered if IgE levels are high, although evidence supporting this approach is weak.[7]

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis typically occurs as an immediate, immunologically mediated reaction after drug exposure but can also present chronically.[3] Figure e48-3A visually depicts a normal alveolus and Fig. e48-3E depicts the parenchymal changes seen in hypersensitivity pneumonitis.

Patients presenting with urticaria, angioedema, rhinitis, conjunctivitis, dyspnea, and bronchospasm after administration of a new drug should raise suspicion for hypersensitivity pneumonitis. Diagnosis is made based on a detailed history of drug exposure and the timing of symptom onset. Pneumonitis can precipitate severe asthma exacerbations requiring urgent intervention to avoid respiratory failure and need for mechanical ventilation.[3]

Causative agents classically include nonsteroidal anti-inflammatory drugs (NSAIDs) and methotrexate.[3,8]

Hypersensitivity pneumonitis is managed by discontinuing the suspected precipitating drug. Supportive care includes the administration of corticosteroids and antihistamines to blunt the immune-mediated and allergic response.[3]

Noncardiac Pulmonary Edema

Although the pathogenesis of noncardiac pulmonary edema is generally unknown, it may result from capillary leak syndrome, hypervolemia, or as a consequence of anaphylaxis.[9] Figure e48-3A visually depicts a normal alveolus and Fig. e48-3F depicts the parenchymal changes seen in noncardiac pulmonary edema.

The clinical presentation is similar to pulmonary edema from acute respiratory distress syndrome and cardiogenic etiologies. Patients present with chest discomfort, dyspnea, tachypnea, and hypoxemia, sometimes requiring urgent mechanical ventilatory support. Diagnosis is made by ruling out cardiac causes, pulmonary hemorrhage, and infections etiologies. Cardiomegaly or pulmonary vascular changes suggest cardiac involvement. Pulmonary infiltrates on chest X-ray reveal interstitial and alveolar filling. Laboratory monitoring and PFTs do not help establish this diagnosis.[9]

The drug-induced pulmonary edema of a noncardiac origin is uncommon; however, it has been reported more with certain classes of drugs. Chemotherapy (cytarabine, gemcitabine), immunosuppressants (immune globulins, methotrexate, muronomab-CD3), calcium channel blockers, pulmonary vasodilators (epoprostenol, nitric oxide), tricyclic antidepressants, opioids (methadone, morphine), amiodarone, nitrofurantoin, talc, protamine, heroin, cocaine, and radiocontrast dyes have been implicated. Counterintuitively, diuretics such as acetazolamide and hydrochlorothiazide can cause severe idiosyncratic pulmonary edema. Obstetric agents such as oxytocin and selective beta-2-adrenergic receptor agonists have also been implicated with noncardiac pulmonary edema, although this may be more related to fluid overload, underlying cardiac issues, steroid use, or multiple gestations.[9] Opioid analgesics such as morphine and methadone can cause noncardiac pulmonary edema. The mu-antagonist naloxone may also be a culprit. Pulmonary edema is precipitated by a catecholamine surge.[9,54]

Management of noncardiac pulmonary edema is usually conservative; most reactions are mild and self-limiting, with symptoms improving rapidly within 1 to -2 days after stopping the implicated drug. Supportive care with supplemental oxygen and diuretics can be necessary to manage pulmonary edema. The role of corticosteroids has been proposed but evidence supporting its use is questionable. In rare, severe cases leading to respiratory failure, patients may require urgent mechanical ventilation.[9]

Diffuse Alveolar Damage/Diffuse Alveolar Hemorrhage

DAD or DAH involves the accumulation of red blood cells in the alveolar space. DAD may be caused by direct toxicity or may be immune-mediated since systemic manifestations of hypersensitivity (dermatitis, vasculitis) have been observed. Destruction of the alveolar-capillary basement membrane leads to loss of structural integrity in alveolar capillaries, and, less commonly, precapillary arterioles or postcapillary venules. DAH can be induced through coagulation defects.[10] Figure e48-3A visually depicts a normal alveolus, and Fig. e48-3G depicts the parenchymal changes seen in DAD.

The clinical presentation is usually acute, with rapid onset of respiratory failure requiring mechanical ventilation. Some cases may be subacute, with slowly progressing symptoms. The cardinal symptom of hemoptysis is present in most cases, along with cough, and progressive dyspnea. Patients may have a decreased hematocrit and have red blood cells present on BAL. If hemoptysis is not present (occurs in 33% of cases), diagnosis can be confirmed with a chest X-ray of new or unexplained infiltrates, decreased hematocrit, and hemorrhagic BAL.[10]

Immune/hypersensitivity-mediated DAD can be caused by chemotherapy, all-trans-retinoic acid, propylthiouracil, penicillin, sulfasalazine, hydralazine, leukotriene antagonists, and mitomycin. DAD caused by direct toxicity to the alveolar basement membrane has also been seen with chemotherapy/bone marrow transplant, as well as amiodarone, nitrofurantoin, and crack cocaine. DAH related to coagulation defects can be seen with thrombolytics, anticoagulants, platelet glycoprotein Ib/IIIa inhibitors, platelet aggregation inhibitors, dextran 70, and drug-induced thrombocytopenia.[10]

Management of DAD and DAH depends on the underlying etiology, but always involves discontinuation of the offending agent. In DAH, treatment may include reversal of the coagulation defect. Chemotherapy-induced DAD has been reportedly treated with high-dose corticosteroids, although data on the effectiveness of this approach is questionable.[10]

Reactions Involving the Pleura

Pleural reactions are an uncommon manifestation of DIPD. Proposed mechanisms of pathogenesis include hypersensitivity/allergic reaction, direct toxic effect, increased oxygen free radical production, suppression of antioxidant mechanisms, and inflammation resulting from drug exposure.[11]

The presentation consists of pleural effusions, along with pleural thickening, and pleuritic chest pain, with or without parenchymal involvement.

Pleural fluid with >10% nucleated cells (eosinophilia) raises suspicion for a drug-induced etiology. Peripheral eosinophilia sometimes occurs as well but is not present in all cases.[11]

Pleural reactions can be classified broadly as non-lupus-related and lupus-related pleural effusions.

Non-Lupus-Related Pleural Effusion

Sclerotherapy agents, including sodium morrhuate and absolute alcohol are most often implicated with non-lupus-related pleural effusions. In this case, pathogenesis involves inflammation spreading from the esophageal varices injection site to the mediastinal pleura. Effusions present on chest X-ray rapidly within 1 day but also typically resolve spontaneously within one week. Empyema rarely occurs but has been reported.[11]

Otherwise, non-lupus-related pleural effusions can be caused by cardiovascular agents (amiodarone, minoxidil), ergoline agents (methysergide, bromocriptine), chemotherapy (bleomycin, mitomycin, procarbazine, methotrexate, cyclophosphamide, dasatinib), and nitrofurantoin. Management involves the discontinuation of the offending agent. Corticosteroids are often utilized despite the absence of robust data supporting their use. With amiodarone-induced reactions, corticosteroids have been recommended in patients with severe hypoxemia and a significant decrease in diffusion capacity.[11,55]

Cyclophosphamide can cause pleural effusions early (1-6 months after exposure) or late (as late as 6 years after drug discontinuation). Patients present with fever, cough, dyspnea, and fatigue. Early onset pleural effusions may respond to corticosteroids, whereas late-onset is less likely to improve symptoms. The presence of pleural thickening on imaging is a sign of late-onset reaction.[11]

Nitrofurantoin can cause pleural effusions in 5% to 25% of patients within one month of therapy. Clinical presentation includes fever, dyspnea, and cough, with bibasilar alveolar or interstitial infiltrates. More chronic presentation results in permanent compromise of lung function and potentially progressive decompensation despite cessation of nitrofurantoin. This is hypothesized to be a consequence of pleural thickening and fibrosis.[11]

Lupus-Related Pleural Effusion

Lupus-related pleural effusions encompass the drug-induced reports of lupus-like reactions or lupus flares. More than 80 drugs have been implicated in this type of reaction since the first description of this in 1945, after the administration of sulfadiazine.[11]

The clinical presentation is similar to idiopathic lupus, which is described in Chapter 107 (Systemic Lupus Erythematosus). This is characterized by exudative effusions, with cell counts of 200 to 15,000 cells/mL (0.2 ~ 10^6/L to 15 ~ 10^6/L), glucose typically in the normal to low range, antinuclear antibodies (ANA) higher than serum values (frequently > 1:250), and presence of lupus erythematosus cells.[11]

Procainamide is the most common causative agent. Ninety percent of patients taking procainamide will have a positive ANA after one year of therapy, and one-third develop a lupus-like syndrome. Onset can occur between 1 month and 12 years from the start of therapy. Importantly, slow acetylators of the drug are at risk for developing the ADR at lower doses and earlier after starting therapy. Hydralazine also carries a relatively high risk for drug-induced lupus, at a rate of 2% to 21%. One-third of patients present with pleural effusions, with once again greater risk for slow acetylator phenotypes, patients receiving higher doses, and longer durations of therapy. Other drugs that have been implicated include chlorpromazine, isoniazid, D-penicillamine, methyldopa, and quinidine.[11]

Reactions Without Direct Toxic Effect to the Lung Tissue

While DIPD caused by direct damage to lung tissue is relatively rare, pulmonary diseases from indirect effects of medication are much more common. Such indirect effects may include aspirin-induced bronchospasm, angiotensin-converting enzyme (ACE) inhibitor-induced cough, and opioid-induced respiratory depression.

Drug-Induced Asthma/Bronchospasm

Rarely, drugs can induce bronchospasm and asthma. Proposed pathogenesis involves inhibition of cyclooxygenase, forcing the metabolism of arachidonic acid through the lipogenesis pathway. This increases the resulting concentration of leukotrienes. The greatest risk factor is preexisting asthma, but older patients, smokers, and those with other preexisting airway diseases are also at risk for developing drug-induced bronchospasm. Causative agents include acetaminophen, aspirin, NSAIDs, and iodinated radiocontrast dyes. About 50% to 100% of patients with asthma develop symptoms of bronchospasm after one dose of a non-selective beta-adrenergic receptor antagonist.[12] Systemic N-acetylcysteine (intravenous in particular) rarely causes bronchoconstriction due to an anaphylactoid reaction.[56] When administered by inhalation, it can also cause direct irritation to the airway, leading to increased airway resistance and bronchoconstriction.[12,57]

Drug-Induced Cough

Angiotensin inhibitor-induced cough occurs in about 10% of patients, with a greater risk for females and non-smokers. Patients present with a persistent, dry cough and "tickle" sensation in the throat. This ADR can occur within hours to months of starting therapy. The pathogenesis is proposed to be related to the accumulation of bradykinin or substance P. Patients are managed by discontinuation of the drug, with improvement typically observed over the course of 1 to 4 weeks.[13]

Calcium channel blockers can also cause cough through relaxation of the lower esophageal sphincter, thereby leading to reflux of gastric contents. Fentanyl intravenous bolus has been hypothesized to cause cough by increasing vagal tone by decreasing central sympathetic outflow or induction of pulmonary chemoreflex. Cough with fentanyl has been reported at rates of 18% to 65%. Latanoprost ophthalmic drops have been hypothesized to upregulate the cough reflex systemically.[13]

Drug-Induced Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH) (see Chapter 46) and the comprehensive clinical presentation and diagnostic criteria are included there. Drug-induced PAH has been observed with anorectic agents, amphetamines, and dasatinib. Newborns of mothers taking selective serotonin reuptake inhibitors during pregnancy are at risk for developing PAH.[14,15]

Drug-Induced Thromboembolic Disorders

It is often challenging to distinguish between PAH and pulmonary veno-occlusive disease, but drug-induced thromboembolic disorders are important to consider in the clinical differential. Refer to Chapter 38 (Venous Thromboembolism) for a comprehensive review of venous thromboembolism (VTE) and pulmonary embolism (PE). Drug-induced causes of thromboembolic disease include chemotherapy (bleomycin, cyclophosphamide, alkylating agents, mitomycin).[15] High-dose combined oral contraception (>50 mg ethinyl estradiol) is no longer available in the United States due to the increased risk for VTE and PE.[58] A VTE incidence of 10% shows with immune checkpoint inhibitors (ipilimumab, pembrolizumab, nivolumab), likely due to effects related to autoimmunity.[16]

Drug-Induced Respiratory Depression or Apnea

Drug-induced respiratory depression or apnea can be unintentional or intentional, such as the facilitation of patient-ventilator synchrony. This can occur via central nervous system (CNS) depression leading to hypoventilation, or neuromuscular blockade, completely blunting patient-initiated respirations.[3]

Opioids for the treatment of pain or in abuse scenarios are often implicated in CNS depression-mediated respiratory depression and/or apnea. Opioids cause respiratory depression by decreasing the sensitivity of peripheral chemoreceptors to carbon dioxide and by decreasing neuronal activity in central respiratory centers.[19] Concomitant administration of other CNS depressants increases the risk for respiratory depression. Other important risks noted in hospitalized patients include renal failure, advanced age, and patients within the first 24 hours of opioid initiation.[18]

Chemical paralysis with a neuromuscular blocking agent blunts respiratory function through skeletal muscle relaxation by stopping the transmission of neuronal impulses at the neuromuscular junction.[17] These agents are used intentionally to facilitate endotracheal intubation and promote patient-ventilator synchrony in patients. However, an important consideration is that the use of neuromuscular blocking agents has been associated with an increased risk for postoperative weakness and difficulty weaning off the ventilator.[59]

Drug-Induced Chest Wall Rigidity

Muscle rigidity and decreased compliance have been observed as an ADR with opioid administration. Although this can occur with any muscle group, when it involves respiratory muscles, laryngeal structures, or chest wall, it can lead to severe complications and require endotracheal intubation for mechanical ventilatory support. The mechanism is related to the stimulation of alpha-2 adrenergic receptors and serotonin receptors. Accordingly, synthetic opioids with greater serotonin activity (fentanyl, remifentanyl, methadone) have been implicated with chest wall rigidity, although it has been seen with other opioids, such as morphine. An incidence of 50% has been reported in healthy male volunteers receiving a 15 mcg/kg dose of fentanyl infused at 150 mcg/min. Drug-induced rigidity is believed to be dose-related, although it can also be seen at lower doses.[19]

CONCLUSIONS

DIPD is an uncommon complication of drug therapy that can lead to significant symptoms, including acute respiratory failure. Many drugs have an indirect effect on lung function, such as respiratory depression associated with opioids, bronchospasm associated with aspirin, or cough associated with ACE inhibitors. Direct toxicity is less common. DIILD, specifically pneumonitis and fibrosis, is the most common manifestation of DIPD with direct lung injury.

DIPD is a diagnosis of exclusion. Many drugs have been reported to cause pulmonary complications. A detailed drug history and documentation of the temporal relationship between exposure and clinical presentation are key to either identifying or ruling out an offending agent. Risk factors for DIPD based on the suspected etiology can also point to the potential likelihood of DIPD. Preventative strategies include avoiding causative agents in high-risk patients and limiting the duration of exposure. Early identification of DIPD is crucial. Management involves the discontinuation of the offending agent. The data for corticosteroids for most DIPD scenarios are weak, although they are commonly used in practice. Supplemental oxygen and mechanical ventilation are supportive therapies used in severe cases.

ABBREVIATIONS

ACE	angiotensin-converting enzyme
ADR	adverse drug reaction
AEP	acute eosinophilic pneumonia
ANA	antinuclear antibodies
BAL	bronchoalveolar lavage
BIP	bleomycin-induced pneumonitis
BOOP	bronchiolitis obliterans organizing pneumonia
CEP	chronic eosinophilic pneumonia
CNS	central nervous system
CRP	c-reactive protein
CTCAE	Common Terminology Criteria for Adverse Events
CT scan	computerized tomography scan
DAD	diffuse alveolar damage

DAH	diffuse alveolar hemorrhage
DIILD	drug-induced interstitial lung disease
DIPD	drug-induced pulmonary diseases
DLCO	diffusing capacity of carbon dioxide
EGFRI	epidermal growth factor receptor inhibitor
ESR	erythrocyte sedimentation rate
HRCT	high-resolution computed tomography
ICPi	immune checkpoint inhibitor
ILD	interstitial lung disease
IPF	idiopathic pulmonary fibrosis
mTORi	mechanistic target of rapamycin inhibitor
NCCN	National Comprehensive Cancer Network
NSAID	nonsteroidal anti-inflammatory drug
PAH	pulmonary arterial hypertension
PE	pulmonary embolism
PFT	pulmonary function test
VTE	venous thromboembolism

SELF-ASSESSMENT QUESTIONS

1. Which of the following factors is associated with an increased risk of amiodarone-induced lung disease?
    A. Concomitant oxygen supplementation
    B. History of current tobacco smoking
    C. Age less than 40 years
    D. A maintenance daily dose greater than 400 mg
2. Which of the following is the most appropriate strategy to monitor for the onset of bleomycin-induced lung disease?
    A. High-resolution computed tomography (HRCT) twice per month
    B. Carbon monoxide diffusing capacity (DLCO) monthly
    C. Bronchial alveolar lavage (BAL) after three months
    D. Physical exam to inspect for cyanosis weekly
3. Which of the following is the most appropriate initial treatment for drug-induced interstitial lung disease?
    A. Discontinue the suspected offending agent
    B. Refer for lung transplantation consult
    C. Initiate a low-dose course of steroids
    D. Provide supplemental oxygen therapy
4. Which of the following is the most appropriate strategy for the early identification of drug-induced interstitial lung disease?
    A. Perform imaging in high-risk patients only if symptoms are present
    B. Educate patients on common symptoms of DIILD before initiation of therapy
    C. Measure eosinophils and erythrocyte sedimentation rate monthly while on therapy
    D. Obtain baseline bronchial alveolar lavage (BAL) with biopsy
5. Which of the following patients is *least likely* to meet diagnostic criteria for DIILD?
    A. Prescribed everolimus for breast cancer; presents with "ground glass" opacities on HRCT, which resolve after discontinuation of everolimus
    B. Prescribed methotrexate for psoriasis; presents with cough and expiratory crackles 6 months after initiating methotrexate
    C. Prescribed docetaxel for prostate cancer; presents with reduced DLCO from baseline
    D. Prescribed ipratropium for COPD; presents with chronic dyspnea and cough
6. Which of the following drug-induced pulmonary diseases can have both an acute and chronic presentation?

A. Bronchospasm

B. Chest wall rigidity

C. Eosinophilic pneumonia

D. Apnea

7. Which of the following is the most appropriate strategy for *immediate* treatment of drug-induced pulmonary diseases in a patient who is oxygenating well and being managed as an outpatient?

A. Initiate supplemental oxygen

B. Investigate drug causes

C. Initiate dexamethasone

D. Discontinue new medications

8. Which of the following patients is most likely to develop drug-induced bronchospasm?

A. 89-year-old with asthma receiving intravenous carvedilol

B. 26-year-old with acute liver failure receiving intravenous N-acetylcysteine

C. 68-year-old with chronic myeloid leukemia receiving oral dasatinib

D. 56-year-old with chronic obstructive pulmonary disease receiving furosemide

9. Nitrofurantoin-induced chronic eosinophilic pneumonia (CEP) with low IgE levels would be most appropriately managed using which of the following strategies?

A. Discontinue nitrofurantoin and initiate prednisone

B. Discontinue nitrofurantoin and initiate albuterol

C. Decrease the dose of nitrofurantoin, initiate dexamethasone and omalizumab

D. Decrease the dose of nitrofurantoin and initiate dexamethasone

SELF-ASSESSMENT QUESTIONS-ANSWERS

1. **D.** Daily and cumulative drug exposure are risk factors for amiodarone-induced DIPD. See "Risk Factors" section for more information. While smoking and oxygen use increase the risk of DIILD for certain agents, they are not correlated with amiodarone toxicity. Advanced age is a risk factor for amiodarone-related pulmonary toxicity—not age under 40 years.

2. **B.** The manufacturer of bleomycin recommends monitoring DLCO monthly to assess the efficiency of lung gas transfer. See the "Prevention and Monitoring" sections for further details. Plain film imaging is preferred over HRCT for routine monitoring. BAL is typically only performed to rule out other causes of pulmonary disease or differentiate between types of interstitial lung disease. Cyanosis typically is not present at disease onset as it develops after disease progression.

3. **A.** The first step in treating DIILD is to remove the offending agent. See the "Management and Treatment" section for more information.

4. **B.** Patients should be informed of the signs and symptoms of DIILD before starting high-risk therapy so that they may self-monitor in between clinician visits. See the "Monitoring, Recognition, and Assessment" section for further details.

5. **D.** The likelihood of DIILD is increased if the patient has been exposed to an agent known to cause the disease. Ipratropium does not cause DIILD. Diagnosis is also more likely if other causes of lung disease can be excluded. COPD is a lung disease that may present similarly to certain DIILD.

6. **C.** Bronchospasm, chest wall rigidity, and apnea present as acute reactions, whereas eosinophilic pneumonia can present acutely or chronically after drug exposure. See Table e48-1 for more information.

7. **B.** The most appropriate strategy for managing drug-induced pulmonary diseases is to review the patient's medication list and identify the most likely inciting drug based on history and presentation. Discontinuing all new medications without regard to the likelihood of causing the pulmonary disease can have unintended adverse consequences related to drug withdrawal. Although supplemental oxygen and corticosteroids may be required for management, they would typically not be needed for immediate treatment in a stable outpatient.

8. **A.** More than 50% of patients with asthma develop bronchospasm after one dose of a non-selective beta-adrenergic receptor antagonist such as carvedilol. Advanced age is also another risk factor for drug-induced bronchospasm. N-acetylcysteine is most likely to cause bronchoconstriction when inhaled, and even then, the risk is relatively low. Dasatinib and furosemide have not caused bronchospasm. Although chronic obstructive pulmonary disease can increase the risk for bronchospasm, this risk would be higher in a patient with asthma.

9. **A.** CEP is best treated by discontinuing the inciting agent, in this case, nitrofurantoin. Corticosteroids are commonly used in conjunction for both CEP and acute eosinophilic pneumonia. When IgE levels are high, omalizumab can also be considered. Bronchodilators have no specific role in CEP.

Chapter e49: Evaluation of the Gastrointestinal Tract

Keith M. Olsen

KEY CONCEPTS

KEY CONCEPTS

① The patient history is key to evaluating gastrointestinal (GI) tract disorders and should include the problem onset, the setting in which it developed, and its presentation. Patient warning signs and alarm symptoms should be identified quickly and referral for further evaluation should be obtained in a prompt manner.

② A complete physical examination should be performed, the severity and location of symptoms directing the focus of the examination.

③ Contrast agents, barium sulfate and Gastrografin® (diatrizoate meglumine and diatrizoate sodium solution), have gradually been replaced by endoscopy, but allow evaluation of the hollow organs of the digestive tract for mucosally based lesions as well as narrowing or strictures involving the GI tract.

④ The upper GI series involves radiographic visualization of the esophagus, stomach, and duodenum; whereas the lower GI series involves visualization of the colon and rectum.

⑤ Enteroclysis is used to evaluate the small bowel by introducing contrast agents by tube through the nose or mouth directly into the small intestine.

⑥ Transabdominal ultrasound, computed tomography, and magnetic resonance imaging provide images of the gallbladder, liver, pancreas, and abdominal wall and are increasingly utilized for assessing small bowel and colonic diseases.

⑦ Radionuclide imaging is sometimes useful to visualize and evaluate the liver, spleen, bile ducts, and gallbladder.

⑧ The endoscope, an illuminated optical instrument, remains the cornerstone of GI diagnosis and most importantly therapy. Common examples of endoscopic procedures include esophagogastroduodenoscopy, colonoscopy, enteroscopy, endoscopic retrograde cholangiopancreatography, and endoscopic ultrasound.

⑨ Capsule endoscopy, a newer less invasive endoscopic technique, takes pictures of the GI tract in the assessment of the small bowel in particular.

⑩ Ambulatory esophageal pH measurement is an important diagnostic test for gastroesophageal reflux disease and is often performed in conjunction with upper endoscopy. Most systems today are completely wireless and patient friendly.

⑪ Multichannel intraluminal impedance and pH monitoring combines acid exposure with impedance changes in resistant flow to aid the diagnosis of reflux in patients receiving a proton pump inhibitor and other antisecretory medications.

BEYOND THE BOOK

BEYOND THE BOOK

This activity will encourage students to review the chapter to determine the most useful approach for diagnostic or therapeutic interventions for each gastrointestinal disease. With each of the following gastrointestinal diseases, determine which laboratory, radiologic, mechanical test, or patient history is required to confirm the diagnosis; unexplained diarrhea, bowel obstruction, Barrett esophagus, reflux disease treated with a proton pump inhibitor.

INTRODUCTION

The GI tract is an organ system responsible for nutrient absorption, waste excretion, and immunity. It is composed of the upper GI tract (oral cavity, esophagus, and duodenum), lower GI tract (small intestine, cecum, colon, rectum, and anus), and associated glandular organs (gallbladder, pancreas, and liver). A variety of symptoms can arise from GI tract dysfunction, including heartburn, dyspepsia, abdominal pain, nausea, vomiting, diarrhea, constipation, and GI bleeding. Signs and symptoms of malabsorption, hepatitis, and GI infection are also commonly seen. All clinicians must recognize warning or alarm symptoms including weight loss, intractable vomiting, anemia, dysphagia, odynophagia, and bleeding; and a patient presenting with any of these symptoms should be immediately referred for further diagnostic interventions.

Despite the rapid proliferation of technology for the diagnosis of digestive diseases, the patient history and physical examination remain important for initial assessment, triage, and guidance of further diagnostic interventions. When combined with a thorough patient history and physical examination, diagnostic procedures are essential in the evaluation of GI disorders. This chapter describes the most commonly used clinical tools to evaluate patients with GI tract-related diseases.

PATIENT HISTORY

① A comprehensive patient history is the cornerstone in the evaluation of a patient with digestive complaints. The purpose of history taking is to obtain a clear and detailed account of the patient's complaints. It is considered the first step in the diagnostic workup and used to narrow the focus of the diagnostic and therapeutic plan for the patient. In addition to collecting information on current complaints, a thorough patient history should gather information concerning medical history, social and family history, and current medications. The healthcare professional should ask guided questions focused on determining the symptom's onset, location, severity, and duration, setting in which symptoms developed, aggravating and alleviating factors, and associated symptoms of the complaint. The symptom onset often provides important information that helps formulate a differential diagnosis. For example, biliary colic or pain, such as that encountered with symptomatic gallstone disease, typically evolves over minutes and is present for hours, but pain caused by pancreatitis evolves over hours and lasts for days. The setting is always relevant as it provides clues to the possible origin of the disorder. For example, in the patient with complaints of reflux or ulcer disease, obtaining information as to whether the pain is alleviated or worsened by food or diminished when administered acid-suppressive therapy can help guide diagnostic and therapeutic interventions. For instance, ingesting a meal often relieves the pain of duodenal ulcer, but worsens pain due to a gastric ulcer. The healthcare professional should ask questions that address potential etiologic possibilities, including motility disorders, structural diseases, malignancies, infections, psychosocial factors, dietary factors, and travel-associated diseases.[1,2] A good cardiopulmonary history is also extremely relevant and should be performed during the overall history. Questions concerning medical and family history detailing illnesses, surgical interventions, injuries, foreign travel, living conditions, and habits are valuable (Table e49-1). A complete medication use history including over-the-counter, herbal, and traditional Chinese medicines is vital as many agents cause GI injury (Table e49-2).

TABLE e49-1

General Questions in a GI History

1. Where is your pain located? Please point to the area where you feel pain. How rapidly did the pain come on? Is your pain constant or intermittent? What factors exacerbate or alleviate your pain? Does the pain awaken you at night?
2. Tell me about the problem that you are experiencing. When did it start? What were you doing when the symptoms began?
3. Have you recently had a change in bowel habits? Have you experienced any diarrhea or constipation lately? Do you experience painful bowel movements?
4. Have you experienced any nausea or vomiting lately? If so, please describe conditions centered on this event.
5. Have you experienced any recent change in weight? Was this intentional? How many pounds have you gained or lost and over what time period did this occur? How has your appetite been?
6. Have you passed any blood from your rectum or vomited blood? Have you noticed any dark, tarry stools?
7. Have you had any acid indigestion?
8. Do you have difficulty swallowing?
9. Have you had these symptoms in the past?
10. What medications are you taking to help alleviate the pain? How much do you take? Do these medications work?
11. Have you recently had a change in dietary intake? If so, please describe. Can you draw any correlation between the foods that you eat and your GI complaint?
12. Describe your medical history, including illnesses and surgeries.
13. Please describe any past injuries that you have experienced.
14. What other medications are you currently taking? Why are you taking them?
15. Has anyone in your family experienced similar GI complaints? If so, please describe. Does anyone in your family have a history of GI disorders, including cancer of the GI tract?
16. Have you recently traveled outside of the United States? If so, where? When? How long did you stay? What kind of living conditions did you experience? What foods and drinks did you ingest?

GI, gastrointestinal.

PHYSICAL EXAMINATION

② A thorough physical examination, not limited to the GI tract, is necessary to provide important diagnostic data and determine the need for acute intervention.[8] A comprehensive evaluation of the patient should be performed with notable attention to physical appearances and vital signs as they may suggest signs of systemic conditions eliciting GI symptoms. An abdominal examination is an essential part of the GI workup and classically includes inspection, auscultation, percussion, and palpation in this order. Inspection of the abdomen may reveal scars, hernias, bulges, or peristalsis. Auscultation is mainly focused on analysis of bowel sounds and identification of bruits and should be performed prior to percussion and/or palpation. Percussion of the abdomen allows for detection of tympany, measurement of visceral organ size, and detection of ascites. Palpation may allow the examiner to identify tenderness, rigidity, masses, and hernias. Moving from the abdominal examination, the digital rectal examination is used to detect rectal masses and tenderness, and to assess muscle tone. Stool on the examiner's glove obtained during rectal examination is often subjected to testing for detection of occult blood.[2,8] Additionally, once cardiovascular disease is eliminated, patients with chest pain may have a GI source to their symptoms and further diagnostic workup may be needed.

LABORATORY AND MICROBIOLOGIC TESTS

Laboratory and microbiologic tests may be used to assess organ function, to screen for certain GI disorders, and to evaluate the effectiveness of therapy. Laboratory testing should be viewed largely as supportive to an accurate history and physical examination. To achieve an accurate diagnosis and provide the best care, it is important to assess the patient's fluid and electrolyte status, nutritional status, inflammatory markers, and abdominal organ function. A complete blood cell count should be completed early in the evaluation to provide information concerning infection, malignancy, bone marrow suppression, anemia, and blood loss.[9] A serum chemistry panel provides valuable information—involving several organ systems. For example, serum creatinine and blood urea nitrogen are often used as a measure of hydration status, as well as, serving as indicators for renal function. Elevations in serum creatinine and blood urea nitrogen may be indicative of renal dysfunction or dehydration, and bleeding from the upper GI tract may lead to elevations in blood urea nitrogen. Albumin and prealbumin levels can be used to assess the patient's nutritional and hydration status and provide information concerning hepatic and renal function. Low albumin may be indicative of malnutrition, hepatic dysfunction, nephrotic syndromes, or protein-losing enteropathies. Serum measurements of sodium, chloride, and potassium are useful to determine electrolyte abnormalities associated with diarrheal illnesses. The erythrocyte sedimentation rate and C-reactive protein are nonspecific inflammatory markers that are useful for the diagnosis and management of patients with inflammatory bowel disease.

More specific laboratory blood tests are often useful for classifying pancreaticobiliary disorders. Measurements of serum aspartate transaminase and alanine transaminase are elevated in most diseases of the liver, and serum alkaline phosphatase and bilirubin are often elevated in hepatobiliary disorders involving bile duct blockage and intrahepatic cholestasis. Prothrombin time and international normalized ratio are related to hepatocyte synthesis of vitamin K-dependent clotting factors and serve as indirect measurements of hepatic function. When evaluating patients with suspected pancreatitis, serum and urine measurements of amylase and lipase are important, because these will be elevated in many patients with acute pancreatitis (see Chapter 57, "Pancreatitis").

Microbiologic and related studies are useful in evaluating patients with unexplained diarrhea, abdominal pain, and suspected GI infections. Stool may be examined to detect the presence of bacteria, parasites, or toxins. Pathogens most often responsible for infectious diarrhea and enteritis include bacteria such as *Shigella*, *Salmonella, Escherichia coli, Yersinia*, and *Clostridioides difficile.* Viruses such as cytomegalovirus, especially in patients with acquired immune deficiency syndrome (AIDS), and parasites such as *Entamoeba histolytica* and *Giardia lamblia* are occasionally seen.[10] Patients presenting with watery diarrhea following antibiotic exposure within the previous 3 months should have their stool checked for *C. difficile* toxins A and B. An additional organism *Helicobacter pylori* is a significant factor associated with peptic ulcer disease and mucosa-associated lymphoid tissue (MALT) lymphomas; identification of this organism is critical in patients experiencing upper GI symptoms and is often tested for during upper endoscopy (see Chapter 51, "Peptic Ulcer Disease").[10]

DIAGNOSIS

The patient's history, physical examination, and routine laboratory tests are valuable in establishing a diagnosis, but frequently more specific studies are required to confirm a clinical suspicion. The most appropriate diagnostic study depends on the anatomic region involved, the suspected abnormality, the reliability of the test (eg, sensitivity vs specificity), the patient's overall condition, and the clinical manifestations of the patient. The next sections outline the most frequently used diagnostic studies and procedures and their roles in evaluating the GI tract.

Noncomputer-Assisted Radiologic Studies

Radiologic procedures rely on the differential absorption of radiation of adjacent tissues to highlight anatomy and pathology. It is useful to divide radiologic testing into noncomputer- and computer-assisted procedures. Noncomputer-assisted radiologic procedures important in evaluating the GI tract include plain radiography, upper GI series with small bowel follow-through, lower GI series, and enteroclysis.[11,12]

Plain Radiography of the Gastrointestinal System

Radiographic evaluation of the GI tract often starts with plain films of the abdomen, which are noncontrast radiographs.[12] Specific abdominal structures that may be identified include the kidneys, ureters, and bladder. The esophagus, stomach, small and large intestine, and stones may also be seen. Stones located within the gallbladder body and within the kidney are sometimes seen on plain abdominal films. Plain films are often used initially to evaluate abdominal pain. Clinicians frequently employ plain radiographic fluoroscopy to guide and position other instruments that are used to evaluate and treat GI disorders; an example is the manipulation of dilation devices to treat esophageal strictures. Bowel obstruction and perforation can be seen using plain radiographic techniques; however, the widespread availability of computed tomography (CT) scanning is gradually replacing these techniques.

Contrast Radiography of the Gastrointestinal System

Oral, rectal, and intravenous contrast agents are used in a variety of ways for radiographic imaging of the GI system. Oral contrast agents, such as barium sulfate and other water-soluble contrasts, are commonly used for radiographic studies, such as pharyngographic studies, upper GI series, and small bowel follow-through examinations. Oral contrast agents are routinely used to opacity the GI tract in CT, magnetic resonance imaging (MRI), CT and MRI enterography, and CT- and MRI-positron emission tomography. Barium sulfate enema technique is an established method for evaluating the colon and to opacity the colonic lumen during abdominal and pelvis CT imaging. Contrast agents allow for visualization of biliary and pancreatic ducts during endoscopic retrograde cholangiopancreatography. Contrast agent nephrotoxicity in patients with preexisting renal impairment remains a clinically significant problem. Pretest treatment in high-risk patients with pharmacologic agents has mixed results.

③ Barium sulfate is a water-soluble contrast agent that improves the visualization of the esophagus, stomach, and intestine in a radiographic image.[12] The area where barium localizes appears white on the radiographic film, creating distinctive definition and visual contrast between an organ and the surrounding tissues. Radiographic studies using barium sulfate are commonly referred to as barium esophogram (*barium swallow*) or barium enema studies as barium sulfate is only administered via the oral or rectal route. Barium sulfate is not generally absorbed, and constipation is the most frequent adverse effect reported with its use. Its use is contraindicated in the setting of known or suspected GI tract perforation due to increased risk of peritonitis. Diatrizoate meglumine and diatrizoate sodium solution (Gastrografin®) is an alternative oral contrast agent for use in patients that are unable to tolerate or are allergic to barium sulfate. Barium sulfate and/or Gastrografin® can reveal mucosal defects and lumen size, and are helpful in diagnosing hiatal hernias, strictures along the GI tract, polyps, tumors, and in some cases ulcers. Upper endoscopy is largely replacing contrast studies in the diagnosis of upper GI tract disorders, but in certain instances they can be a tool in establishing a diagnosis prior to endoscopic evaluation. The barium esophogram should not serve as a primary diagnostic tool for patients with heartburn.

Upper Gastrointestinal Series

④ The upper GI series refers to the radiographic visualization of the esophagus, stomach, and duodenum. Patient preparation for an upper GI series usually consists of instructing patients to refrain from eating or drinking 8 to 12 hours prior to testing, which allows the upper GI tract to empty. A contrast agent such as barium sulfate or Gastrografin® is administered to the patient at the beginning of the study. The observed swallowing of the contrast agent permits visualization and monitoring of esophageal structural and motor functions. A gastrointestinal radiologist sometimes uses double contrast techniques to enhance the visualization of the inside wall lining of the esophagus, stomach, and duodenum. The double contrast technique uses a gas, such as air or a carbonated substance, in addition to barium sulfate. The gas expands the organs and allows for the barium sulfate to coat the inner surface of the organ, providing sharpened visualization.[13]

The upper GI series can be continued as the contrast agent moves from the stomach and duodenum into the small intestine, referred to as the *small bowel follow-through*. The single contrast agent technique, with either barium sulfate or a water-soluble contrast, is utilized during a small bowel follow-through. An upper GI series with small bowel follow-through commonly uncovers gastric cancer, peptic ulcer disease, esophagitis, gastric outlet obstruction, and can be suggestive of Crohn's disease (Fig. e49-1). In general, the barium swallow is plagued by low sensitivity and specificity for many GI disorders and as mentioned is being replaced by upper endoscopic techniques.

FIGURE e49-1

Upper GI series with small bowel follow-through demonstrating narrowed distal terminal ileum and separation of small bowel loops (*arrow*). These findings are consistent with Crohn's disease.

Lower Gastrointestinal Series

The lower GI series is used to examine the colon and rectum and is particularly useful if a colonic obstruction is suspected. Patients complaining of lower abdominal pain, constipation, or diarrhea are often referred for a lower GI series, also called a barium enema. The colon is prepared for the procedure by instructing the patient to refrain from eating or drinking 8 to 12 hours before the procedure, and by administering bowel-cleansing agents such as sodium sulfate-based tablets, bisacodyl, magnesium citrate, magnesium hydroxide, or polyethylene glycol electrolyte (PEG) solution. A combination of laxatives and fluids are used for bowel cleansing prior to colonoscopy.[14] During a lower GI series, a barium sulfate enema is given to contrast the terminal large intestine and rectum. The lower GI series is sometimes useful to detect and evaluate enterocolitis, obstructions, volvulus, and mucosal and structural lesions.[12] Similar to the upper GI series, the double contrast technique with air may be used to enhance imaging of the colon.

Small Bowel Enteroclysis

⑤ Enteroclysis, or small bowel enema, refers to the technique of direct small bowel introduction of a contrast agent through a tube inserted through the patient's mouth or nose directly into the small intestine. Sequential radiographic films are taken of the small bowel as the contrast agent flows distally (Fig. e49-2). The enteroclysis technique allows for optimal distention of the small bowel lumen and enables visualization of subtle mucosal abnormalities. Enteroclysis is not widely performed due to operator inexperience and is rapidly being replaced by improved radiologic techniques such as CT or MRI enterography or by small intestinal endoscopy known as single and double balloon enteroscopy and capsule endoscopy.

FIGURE e49-2

Normal small bowel enteroclysis. Contrast agents are instilled into the small bowel to highlight tumors, strictures, or other lesions. In this image, one can identify the normal circular folds.

Computer-Assisted Radiologic Studies

The second category of radiologic evaluation of the GI tract involves computer-assisted techniques, which allow a cross-sectional radiographic image of the body to be performed. Transabdominal ultrasonography, CT, radionuclide scanning, and MRI are frequently used imaging procedures for evaluating digestive disorders.[11,12]

Ultrasonography

⑥ Ultrasonography provides images of deeper structures such as the gallbladder, liver, and kidneys and can also be useful in helping define vascular abnormalities in the intra-abdominal cavity. Ultrasound involves the direction of a narrow beam of high-energy sound waves into the body and recording the reflections from the various organs and structures. In general, ultrasonography is a well-accepted, noninvasive, and relatively inexpensive method for evaluating GI pathology that requires no ionizing radiation and can be performed at bedside with a portable unit. It accurately depicts the presence of gallstones within the gallbladder, helps define liver morphology, and serves as a first test to evaluate the absence or presence of biliary ductal dilation in a jaundiced patient (Fig. e49-3). When combined with Doppler technologies, ultrasonography can image GI vascularity, in particular portal venous flow, and identify aneurysmal dilations of the abdominal aorta. The images produced by ultrasonography are not as sharp and clear as those produced by CT and the quality of the images produced relies heavily on the operator. Ultrasonography is limited by the presence of bowel gas and excessive amounts of body fat, particularly when evaluating deeper organs such as the pancreas.[11,12]

FIGURE e49-3

Computed Tomography

Advances in CT or computed axial tomography (CAT) scanning have resulted in a paradigm shift for chest and abdominal-pelvic imaging, providing improved resolution and faster acquisition of radiographic information. A CT examination provides detailed images of the GI system in which transverse planes of tissue are swept by a radiographic beam and a computer analysis of the variance in absorption produces a precise reconstructed image of that area.[11] Contrast agents may be added during a CT procedure to enhance the difference in density of various structures. Oral and rectal administration of a contrast agent, such as barium sulfate or a water-soluble contrast agent, will help delineate the GI tract; while intravenous administration of a water-soluble contrast agent will illuminate the vascularity of the GI tract.

The abdominal CT displays organs from the diaphragm down to the pelvic brim, and is especially valuable for detecting GI diseases of the liver, pancreas, spleen, and colon. Patient preparation for CT includes refraining from eating or drinking for a minimum of 4 hours before the test. The remarkable detail that CT offers in imaging of organs and tissues adds to its popularity for evaluation of the GI tract. CT scanning is rapidly replacing plane radiography of the abdomen due to its widespread availability, diminishing cost, and wealth of information provided. CT is also useful in the identification of suspected intra-abdominal malignancy, pancreatitis, intra-abdominal abscesses, and cysts (Fig. e49-4).[11,12] Unlike ultrasonography, patient body size or the presence of gas does not limit the quality of imaging with CT. Contrast agents used during CT scanning are nephrotoxic and close attention to a patient's renal function is mandatory in these patients.

FIGURE e49-4

CT enteroclysis combines the methods of barium enteroclysis and abdominal CT into one technique. It is highly accurate in depicting mucosal abnormalities in Crohn's disease and diagnosing of low-grade small bowel obstructions. During CT enteroclysis, the small bowel is expanded by introduction of a contrast agent through a nasoduodenal tube directly into the small intestine with or without intravenous contrast. CT enterography uses the same method as CT enteroclysis; however, the patient orally ingests the contrast agent without the use of a nasoduodenal tube. For the investigation of small-bowel disease, CT enteroclysis is considered a complementary addition to capsule endoscopy technique discussed later in this chapter.[15]

Radionuclide Imaging

⑦ Radionuclide imaging, commonly referred to as nuclear medicine, is a well-suited diagnostic tool that allows for structural and functional visualization of the GI tract. It involves IV injections of a radiopharmaceutical imaging agent and the use of a computerized detection camera to gather images. A secretory agent is sometimes given in addition to the radiopharmaceutical agent to improve sensitivity. Although the choice of a radiopharmaceutical agent depends on the specific organ or function being studied, the most commonly used agent is technetium (^{99m}Tc) tagged to a carrier molecule. Radionuclide imaging is sometimes useful to visualize the liver and spleen (liver–spleen scan), bile ducts, gallbladder (hepatoiminodiacetic acid [HIDA] scan), and gut (tagged red blood cell).[11,12] Cysts, abscesses, tumors, and obstructions are detected and displayed as areas of differential uptake of radioactivity.[11] Radionuclide bleeding scans may detect hemorrhages and may assist with localization of therapeutic interventions. Patient preparation for radionuclide imaging includes refraining from eating or drinking for a minimum of 8 hours before the test.

Magnetic Resonance Imaging

MRI allows for a comprehensive evaluation of intra-abdominal solid organs including, the liver, pancreas, and spleen, without the use of ionizing radiation. An MRI places the patient in close proximity to a high-strength magnetic field through which pulses of radiofrequency radiation are projected, thereby exciting the nuclei of hydrogen, phosphorus, oxygen, and other elements. The radiofrequency signals are manipulated and recorded by a computer, and a two-dimensional image representing a section of the patient is produced.[11,12] MRI has greater sensitivity for identifying liver tumors than do ultrasonography, CT, and radionuclide imaging. Patient preparation for an MRI includes refraining from eating or drinking for a minimum of 4 hours before the test. Significant advances in MRI technology and imaging capabilities often make it a preferred diagnostic test, particularly in the evaluation of pancreaticobiliary disorders when secretin is added to enhance bile and pancreatic duct visualization.[11,12] Magnetic resonance cholangiopancreatography (MRCP) is used for evaluating the biliary tract and pancreatic duct in a noninvasive manner without the need for exogenous contrast agents. In MRCP, static fluid in the ducts appears bright against the darker tissue.

Similar to CT, magnetic resonance enteroclysis and enterography are used to evaluate and monitor patients with Crohn's disease. Due to the lack of radiation exposure, magnetic resonance enteroclysis offers an advantage over CT enteroclysis particularly in younger patients that will likely require numerous examinations over their lifetime. However, it appears to be less accurate than CT enteroclysis which has higher sensitivity.[15]

Arteriography

Arteriography of the gut depicts the configuration of visceral blood vessels after intravascular administration of an iodinated contrast agent. Arteriography may be employed for vascular anomalies such as an aneurysmal dilation and in the evaluation of obscure bleeding lesions. The therapeutic applications for arteriography include, embolization of bleeding vessels, fistulas, and inoperable tumors.[11,12]

Endoscopy

⑧ Refinement in optical engineering and fiber optics led to the development of the endoscope, which has revolutionized the management of GI disorders. Most endoscopic equipment today uses a computer chip device to provide high definition, detailed images of the particular lumen being examined. An endoscope is an illuminated white light and non-white light optical instrument designed to inspect the interior of the GI tract. Endoscopes enable the practitioner to inspect intraluminal mucosal lesions and to obtain biopsies, washings and brushings for cytology studies. Standard upper GI tract endoscopy (ie, esophagogastroduodenoscopy [EGD]) is capable of inspecting the esophagus, stomach, and proximal small bowel. Lower GI tract endoscopic evaluation of the rectum and colon may be accomplished by colonoscopy or flexible-sigmoidoscopy. In addition to standard upper and lower endoscopy many newer diagnostic and therapeutic endoscopic devices are now available.[16]

Patients should be instructed to refrain from eating or drinking for at least 8 to 12 hours prior to the endoscopic procedure. Bowel cleansing is necessary for colonoscopy and sigmoidoscopy using a variety of PEG-based solutions. Topical pharyngeal anesthetics, such as viscous lidocaine or benzocaine, usually improve patient acceptance of the upper endoscopic tube. Intravenous sedating agents, such as lorazepam and midazolam, are commonly used to induce a state of altered consciousness, referred to as conscious sedation that minimizes discomfort during the endoscopic procedure. These sedating agents tend to improve patient acceptance and ease of the procedure. The agents should not be used without appropriate monitoring and the availability of flumazenil, a benzodiazepine antagonist. Propofol has been used to induce a deeper sedation than traditional sedation agents and improves patient comfort and shortens recovery and discharge time.[17] Propofol has a negative cardiac inotropic effect which can cause a decrease in cardiac output, vascular resistance, and arterial pressure, and can induce respiratory depression in a dose-dependent fashion. The potential for serious adverse events with these agents used for sedation during endoscopic procedure should be considered and patients should be monitored appropriately. Antimuscarinic agents, such as atropine sulfate, are occasionally used to increase a patient’s heart rate and reduce duodenal and colonic motility. Glucagon may be used to reduce bowel motility. Endoscopy should be pursued with caution in patients with severe respiratory or cardiac failure, and endoscopy is contraindicated for patients with suspected perforated viscera. The most commonly used endoscopic studies are upper endoscopy (EGD), colonoscopy, flexible sigmoidoscopy, and endoscopic retrograde cholangiopancreatography (ERCP).[16] Newer endoscopic techniques include single or double balloon enteroscopy, capsule endoscopy, and endoscopic ultrasound (EUS). These techniques are outlined in detail below.

Upper Endoscopy

EGD, upper endoscopy, is used to examine the esophagus, stomach, and duodenum. Common indications for EGD include evaluation of suspected upper GI bleeding, obstructions, upper abdominal pain, and persistent vomiting, as well as, evaluation of radiographic abnormalities.[18] Patient preparation for EGD includes refraining from eating or drinking prior to the procedure and the administration of sedatives and topical anesthetics. EGD can also be used therapeutically in upper GI bleeding for ligation procedures involving esophageal varices, sclerosing, or vasoconstrictive agent administration at the site of the bleed in peptic ulcer-induced bleeding, or via the use of a thermal device such as a gold probe or heater probe on a bleeding vessel. In addition to its therapeutic potential, EGD commonly uncovers peptic ulcer disease and is the method of choice to diagnose Barrett esophagus, a premalignant condition of the esophagus and other esophageal ulcer erosive disorders (Fig. e49-5).

Endoscopy may also be used for the diagnosis of eosinophilic esophagitis. A patient with an esophageal biopsy demonstrating at least 15 eosinophils per high power field (HPF) suggest eosinophilic esophagitis in the absence of gastroesophageal reflux disease and other disease processes.[19]

Colonoscopy

Colonoscopy, lower GI endoscopy, permits direct examination of the large intestine and rectum and in addition allows for therapeutic removal of polyps and biopsy diagnosis of suspicious colonic lesions. Colonoscopy represents the main screening modality for the early detection and management of colonic polyps, which, in some cases, represent the precursor lesions for colorectal cancer development. To prepare for colonoscopy, the patient should refrain from eating or drinking for at least 8 to 12 hours prior to the examination, and bowel cleansing should be completed. Bowel preparations have traditionally involved a PEG-based or phosphate-based solution. However, due to concerns regarding phosphate-induced nephropathy, there has been a return to standard PEG-based solutions. Newer trends in bowel preparation mainly include the advent of split dose bowel preparation involving the ingestion of approximately two-thirds of the bowel preparation the night before and the additional one-third 6 hours prior to the schedule procedure. This improves bowel visualization, particularly visualization of the right colon. A benzodiazepine is often given to produce conscious sedation and improve patient comfort. Propofol is often administered to provide a deeper level of sedation in patients who are refractory or intolerant to conscious sedation agents. Indications for lower GI endoscopy can be either diagnostic or therapeutic in nature. Common indications include evaluation and detection of abnormalities visualized by radiography, as well as diagnosis and therapy of GI hemorrhage, and importantly, screening patients for colorectal carcinoma. Colonoscopy remains an invaluable procedure in the diagnosis, staging, and therapy of patients with inflammatory bowel disease (eg, ulcerative colitis and Crohn's disease).[20]

Sigmoidoscopy

Flexible sigmoidoscopy is used to evaluate the sigmoid colon via the anorectum (Fig. e49-6). It has virtually replaced rigid sigmoidoscopy because of increased patient comfort and superior performance. The major indication for this examination is to evaluate symptoms related to the distal colon or rectum, such as hematochezia, painful defecation, and unexplained diarrhea. Flexible sigmoidoscopy is gradually being replaced by full colonoscopy in the evaluation and screening of patients for colorectal carcinoma. Patient preparation involves instructing patients to refrain from eating or drinking for at least 8 hours prior to the procedure and the administering of bowel-cleansing agents. Anoscopy is especially useful in evaluating the anus. The major indications for anoscopic examination include symptoms related to the anus and rectum, such as bleeding, protruding anorectal lesions, pain with defecation, and severe itching. Patients undergoing sigmoidoscopy or anoscopy generally do not require sedation.

Endoscopic Retrograde Cholangiopancreatography

ERCP is an important therapeutic procedure that combines endoscopy and fluoroscopic imaging techniques to evaluate and treat diseases of the pancreaticobiliary tree. Common indications for ERCP include common bile duct stone management and bile and pancreatic duct stricture management, as well as, diagnosis and therapy of biliary tract and/or pancreatic malignancies. Cannulation of the bile or pancreatic duct is achieved through the wire-guided approach. Once the location of the guide wire has been confirmed, contrast agent is injected into the bile duct which can reveal abnormalities such as obstruction due to malignancy, confirm presence of biliary or pancreatic duct calculi, and improved characterization of biliary strictures. ERCP also provides therapeutic modalities such as biliary or pancreatic sphincterotomy, removal of ductal stones from the common bile duct or main pancreatic duct, and stenting of biliary or pancreatic strictures. ERCP is also a useful method for tissue acquisition in the pancreaticobiliary tract using a variety of brush and biopsy devices. Advances in ERCP include the addition of direct bile duct or pancreatic duct visualization (cholangioscopy and/or pancreatoscopy), a procedure which has greatly aided in the diagnosis and therapy of pancreaticobiliary disorders. Preparation for ERCP consists of glucagon to relax gut motility and conscious sedation which often requires the use of an anesthesiologist due to the complex and long procedural times associated with ERCP (Fig. e49-7).[12,20]

Endoscopic Ultrasound

EUS is a newer endoscopic technology, which represents a marriage between endoscopy and standard ultrasound techniques. A high frequency ultrasound probe is attached to the working end of a diagnostic (radial array) or therapeutic (linear array) oblique viewing echoendoscope. EUS is commonly used to stage and diagnose upper GI tract malignancies such as those involving the esophagus, stomach, and pancreas. Upper GI tract locoregional tumor staging and tissue acquisition is highly sensitive and specific and provides a less invasive manner of tissue acquisition in many cases. Expanded uses of EUS include diagnosis and management of pancreatic fluid collections such as pancreatic cystic neoplasms (nonpseudocystic), celiac plexus block versus neurolysis in pancreatic malignant and chronic pancreatitis patients, and in some centers, direct instillation of antitumor agents into pancreatic malignancies. The development of ultrasound contrast agents, referred to as contrast-enhanced EUS, allows for better visualization of the vasculature and more accurate characterization of detected lesions. Ultrasound contrast agents consist of gas-filled microbubbles encapsulated by a phospholipid shell which oscillate to sound pressure and cause back-scattering of the ultrasound signal.[21] EUS-guided bile duct access is an additional indication gaining popularity in those patients in whom access at ERCP fails or is not technically feasible. Lower GI tract EUS is commonly performed in the diagnosis and locoregional staging of anorectal carcinoma and in evaluation of the anal sphincters. EUS is an invaluable tool in the management of GI tract disorders but its use remains centered largely in academic, tertiary care referral institutions.

Enteroscopy

Enteroscopy, or direct visualization of the small intestine, has traditionally been limited to examination of the proximal most portions of the duodenum/jejunum because of excessive endoscope looping and discomfort to the patient during the examination. To overcome these difficulties, two newer techniques, single and double balloon enteroscopy, have been developed. Sometimes referred to as “deep enteroscopy,” these particular endoscopic procedures involve sequential inflation and deflation of balloon attachment devices in order to sequentially “walk” the enteroscope down the small or large intestine. A combination of inflation, deflation, and endoscope reduction via torque and withdrawal allow for a pleating of the mucosal surface being examined. Complete traversal of the small intestine is routinely achieved via the oral route and significant traversal of the colon and distal small intestine is now possible from the rectal route. Common indications for these procedures include the evaluation of obscure GI bleeding, the diagnosis and evaluation of possible inflammatory bowel disease, and the evaluation of radiologically discovered lesions such as mass or bowel wall thickening. Numerous studies, including some head-to-head trials, have yielded a high sensitivity and specificity for these technologies. The added advantage of deep enteroscopy is the ability to directly observe lesions of interest, to biopsy readily during the procedure, and in cases of obscure GI bleeding to add therapeutic maneuvers such as the application of thermal therapy or argon plasma coagulation to lesions felt to be responsible for ongoing blood loss.

Capsule Endoscopy

⑨ Capsule endoscopy allows the visualization of the esophagus, stomach, and small intestine. This device consists of a vitamin pill-sized video camera that is swallowed and acts as an endoscope (Fig. e49-8). As the video capsule travels naturally through the digestive tract, images are transmitted to a recording device placed on the patient's hip. Patients return the recording device to the practitioner so that the images can be downloaded to a computer and evaluated. Eventually, the camera is naturally excreted and not retrieved.[22] Capsule endoscopy represents a noninvasive means to evaluate the upper and lower GI tracts but unfortunately lacks therapeutic capability. Capsule endoscopy is often used in the evaluation of obscure GI bleeding and in the evaluation of suspected inflammatory bowel disease and is oftentimes used in conjunction with single or double balloon enteroscopy. Capsule endoscopy continues to represent a powerful diagnostic tool in the management of many GI tract disorders.

FIGURE e49-8

Capsule endoscopy images of a mildly scalloped jejuna fold (left) and an ileal tumor (right) in a patient with celiac sprue. *(From Wong-Kee-Song LM, Topazian M. Gastrointestinal endoscopy. MISCELLANEOUS GASTROINTESTIONAL TESTS

Ambulatory Esophageal pH Monitoring

⑩ Esophageal pH monitoring is considered by many clinicians as the gold standard in the evaluation of patients who complain of gastroesophageal reflux. The evaluation of dyspepsia, whether it be organic or functional, is an extremely prevalent GI tract complaint and the use of ambulatory 24-hour pH monitoring is an elegant way to link esophageal acid exposure, as detected by a probe in the esophagus, with patient symptoms. The pH probe is transnasally placed approximately 5 cm above the distal esophagus. Intraesophageal pH is normally higher (pH 6) than that of the stomach (pH approximately 1-3), the pH probe will continuously record any decreases in pH if gastroesophageal reflux occurs. The most accepted method to identify gastroesophageal reflux during monitoring is the sudden decrease in pH below 4.0. The ambulatory 24-hour pH study links the patient's symptom to an acid event (Fig. e49-9). Wireless pH monitoring systems have gradually replaced the older methods that required a wire probe placement. A capsule is attached to the distal esophagus by a delivery system. The capsule then transmits measured pH data to a receiver by a radiotelemetry technique. Wireless systems offer the advantage of better patient acceptance and extended monitoring of up to 96 hours versus 24 hours of the wire method. There are limitations to ambulatory pH monitoring in patients receiving PPI therapy or in the detection of nonacidic or weakly acidic refluxate.[23]

FIGURE e49-9

Ambulatory pH monitoring. The pH recordings from two esophageal probes are plotted over a 3-hour interval. Notice that the patient's symptom of regurgitation correlates with a low pH (<4) event (*arrow*).

⑪ Multichannel intraluminal impedance monitoring is an emerging technique to study acid and nonacid reflux. The method combines pH measurements with manometry that enables the measurement of and distinction between swallowing and reflux. In patients whose symptoms have not responded to empiric PPI therapy in GERD, impedance test can separate those in whom symptoms are associated with acid reflux from those in whom symptoms are associated with nonacid reflux. Outcomes studies are required to further evaluate the usefulness of this diagnostic method; however, accumulating data are extremely promising.[18,24]

Esophageal Manometry

High-resolution esophageal manometry is used to evaluate diseases of the esophagus by assessing esophageal motor functions. Common indications for this procedure include dysphagia and obscure chest pain or patients unresponsive to acid-suppressive therapy not explained by other diagnostic tests. A special catheter equipped with pressure transducers is placed into the esophagus to measure esophageal pressures and peristalsis. Provocative testing with pharmacologic agents such as edrophonium chloride, a cholinergic muscle stimulant, may be used to precipitate esophageal pain during this procedure. Typical indications for esophageal manometry include evaluating suspected esophageal dysmotility, nonobstructive dysphagia, obscure chest pain, intestinal pseudo-obstruction, achalasia, and aiding in the positioning instruments such as pH probes. Esophageal manometry is almost always performed following endoscopic evaluation of the upper GI tract and can be a valuable tool in diagnosing many nonspecific disorders of the upper GI tract.

Laparoscopy

Laparoscopy uses a tube-like device with an elaborate optical system that permits distinct visualization of the peritoneal cavity. General anesthesia is often required and a surgical incision is made in the abdomen to allow the passage of the laparoscope. The exterior of the liver, gallbladder, spleen, peritoneum, diaphragm, and pelvic organs may be examined during the laparoscopic examination. Similar to the other endoscopic techniques mentioned, biopsies and therapeutic interventions may be performed during the laparoscopy. Laparoscopy is extremely invasive. Indications for laparoscopy include evaluation of patients with abdominal masses, chronic abdominal pain of unclear etiology, abnormalities indicated on liver-spleen scan, such as acute or chronic cholecystitis, and the diagnosis and management of intra-abdominal malignancy.

ABBREVIATIONS

CT	computed tomography
EGD	esophagogastroduodenoscopy
ERCP	endoscopic retrograde cholangiopancreatography
EUS	endoscopic ultrasound
GERD	gastroesophageal reflux disease
HPF	high-power field
MRCP	magnetic resonance cholangiopancreatography
MRI	magnetic resonance imaging
PEG	polyethylene glycol electrolyte solution
PPI	proton pump inhibitor

SELF-ASSESSMENT QUESTIONS

1. A patient presenting with watery diarrhea and a history of antibiotic use 2 months ago should have their stool checked for:

   A. *Helicobacter pylori*

   B. *Clostridioides difficile* toxin

   C. *Enterobacter cloacae*

   D. *Escherichia coli* toxin

2. The preferred imaging method to detect an intra-abdominal malignancy is:

A. Small bowel enteroclysis

B. Computed tomography

C. Plain radiography films

D. Barium swallow with radiography

3. In a patient presenting with signs and symptoms of acute liver failure, which of the following agents has been associated with liver damage?

A. Phenytoin

B. Amoxicillin

C. Morphine

D. St. John's wort

4. Bacteria associated with infectious diarrhea include:

A. *Streptococcus pyogenes*

B. *E. coli*

C. *Klebsiella oxytoca*

D. *H. pylori*

5. Serum sodium or potassium abnormalities may be indicative of which of the following GI tract disorders?

A. Diarrheal illnesses

B. Mild hepatic dysfunction

C. Gastroesophageal reflux disease (GERD)

D. Diverticulitis

6. In a patient undergoing a computed tomography study with contrast, which of following adverse events is most commonly associated with the use of a contrast agent?

A. *Clostridioides difficile* infection

B. Leukopenia

C. Hyperkalemia

D. Nephrotoxicity

7. Which test should be used in a patient with suspected reflux disease but not responding to a PPI?

A. Ambulatory pH monitoring

B. Capsule endoscopy

C. Multichannel intraluminal impedance

D. Endoscopic ultrasound

8. Pain associated with pancreatitis usually:
    A. Rapidly develops and resolves within a few minutes.
    B. Typically evolves over hours and last for days.
    C. Is episodical, with complaints occurring only in the morning.
    D. Often presents with gastritis and dyspepsia.
9. An often overlooked assessment of gastrointestinal disease is:
    A. Cardiopulmonary examination
    B. Medication history
    C. Surgical history
    D. Duration and severity of pain
10. A 69-year-old gentleman presents with bleeding from the upper gastrointestinal tract. Which of the following laboratory tests is often elevated in a patient with an upper gastrointestinal tract bleed?
    A. Troponin
    B. C-reactive protein
    C. White blood cell count
    D. Blood urea nitrogen
11. In a patient presenting with signs and symptoms consistent with hepatitis C, which of the following laboratory test is an indirect measurement of hepatic function?
    A. Erythrocyte sedimentation rate
    B. Prothrombin time and international normalized ratio (INR)
    C. Serum creatinine
    D. Atrial natriuretic peptide
12. Prior to colonoscopy, the colon should be prepared by administration of:
    A. Sodium sulfate–based tablets.
    B. Polyethylene glycol electrolyte solution
    C. Magnesium citrate.
    D. A combination of laxatives and fluids.
13. Ultrasonography is a useful diagnostic method to define:
    A. Bleeding gastric ulcer.
    B. Malt lymphoma in the small bowel and colon.

C. Gallstones within the gallbladder.

D. The GI tract in a patient presenting with water diarrhea.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** A patient with a recent history of antimicrobial use and diarrhea should always be suspected of having *Clostridioides* infection. *H. pylori* is generally associated with peptic ulcer disease and does not induce diarrhea. *E. coli* can cause diarrhea, but usually not associated with recent antimicrobial use.

2. **B.** Computer tomography (CT) scan provides improved resolution and faster acquisition of radiographic information. All of the other procedures in this question do not provide the same detail as a CT scan.

3. **A.** Phenytoin is known to cause GI injury. The other medications listed are not.

4. **B.** Only *E. coli* is associated with infectious diarrhea of the pathogens listed. *S. pyogenes* is associated with strep throat and necrotizing fasciitis. *H. pylori* is associated with peptic ulcer disease, and *Klebsiella* is primarily associated with nosocomial systemic infections.

5. **A.** Depending upon severity, diarrhea can result in fluid and electrolyte loss, such as potassium and sodium. Mild to even moderate hepatic dysfunction has modest effects on electrolytes. Electrolyte abnormalities are usually absent in gastroesophageal reflux disease.

6. **D.** Nephrotoxicity is commonly associated with contrast agents. A predisposing factor is underlying renal disease. Although other adverse events have been reported with contrast agents, they have a very low frequency.

7. **C.** If a patient is receiving a PPI, ambulatory pH monitoring, capsule endoscopy, or endoscopic ultrasound may not be able to detect any changes in the esophagus. Multichannel intraluminal impedance is a technique to study acid and nonacid reflux and can be performed on a patient using a PPI.

8. **B.** Because of the underlying pathology in pancreatitis and the resulting tissue damage, pain evolves over hours and may last for days.

9. **A.** The cardiopulmonary exam is often overlooked when evaluating the gastrointestinal tract and liver. Electrolyte shifts and fluid loss are typically found in GI disease and may result in heart abnormalities.

10. **D.** When upper GI bleeding occurs, blood protein is metabolized and converted to urea and then to BUN in the urea cycle. Other labs listed in this question are not directly impacted by GI bleeding.

11. **B.** Prothrombin may be impacted by clotting factors synthesized by the liver. During hepatic disease, a decrease in the clotting factor production may lead to a prolonged prothrombin time and INR. Erythrocyte sedimentation rate may also be elevated in hepatic disease, but is a not specific and more indicative of a chronic disease. Atrial natriuretic factor and serum creatinine are more indicative of cardiac or renal disease, respectively.

12. **D.** Only a combination of fluids and laxatives provides adequate evacuation of the bowel prior to colonoscopy.

13. **C.** Ultrasonography is a noninvasive procedure providing images of deep structures in the gastrointestinal tract, including the gallbladder. The other listed disease states are more diffused and not easily visualized by a high-energy sound wave.

Chapter e56: Drug-Induced Liver Injury

William Kirchain; Rondall E. Allen

KEY CONCEPTS

KEY CONCEPTS

① Through its normally functioning enzymes and processes the liver often causes a drug to become toxic through a process known as bioactivation.

② Drug-induced liver injury (DILI) can have many different clinical presentations: idiosyncratic reactions, allergic hepatitis, toxic hepatitis, chronic active toxic hepatitis, toxic cirrhosis, and liver vascular disorders.

③ The mechanisms of DILI are diverse, representing many phases of biotransformation, and are susceptible to genetic polymorphism.

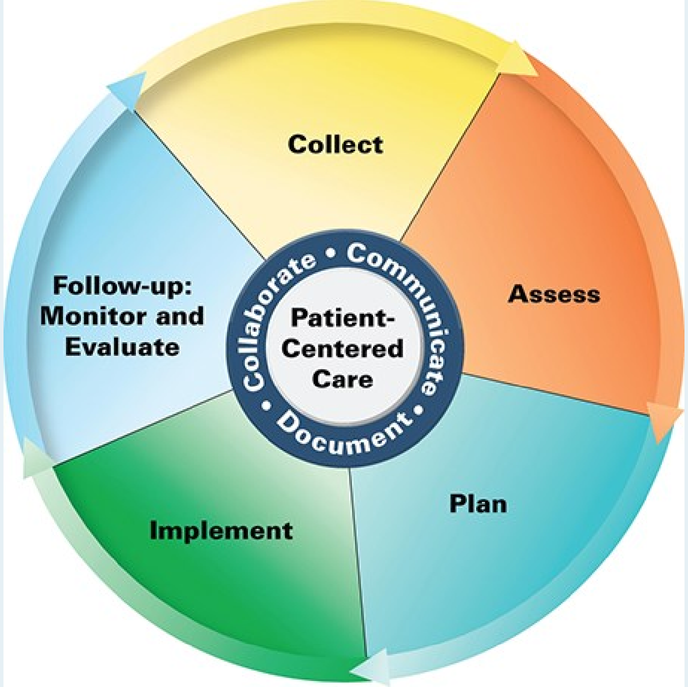
④ The assessment of a possible liver injury caused by drugs should include what is known in the literature, the timing involved, the clinical course, and, always, an exploration for preexisting conditions that may have encouraged the lesion's development.

⑤ Liver enzyme assays in serum can help to determine if a particular type of liver damage is present.

⑥ Monitoring for DILI must be tailored to the drug and the patient's potential risk factors.

PATIENT CARE PROCESS

Patient Care Process for Drug-Induced Liver Injury



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient demographics listing, age, and pregnancy status are very important
- Patient medical history including any possible previous liver injury and illness that may indicate an alternative cause or a predisposition; and type 2 diabetes mellitus that may indicate a nonalcoholic fatty liver
- History of present illness that carefully documents each symptom with a time of onset
- Social history comprising a detailed assessment of alcohol use; intravenous drug use and other recreational substance use; along with a careful work history (see Table e56-3)
- Current medication history that prioritizes those initiated within the last 90 days and includes prescription, nonprescription, herbal, and other complementary medicines. If possible, determine exact time the medication was started prior to patient presentation
- Objective data should include
    - Liver enzyme values, Total Bilirubin, Direct and Indirect Bilirubin
    - Liver function tests, such as INR, transferrin and ammonia
    - Hepatitis A, B, C assessments
    - Objective confirmation of liver injury via biopsy, CT, MRI, or sonogram
- A literature search for reports of the patient's medications, herbs used and other substances, and liver injury
- A search of liver injury reports on LiverTox

Assess

- The pattern of liver enzyme elevation (see Table e56-4)
- The probability of each likely agent as a causative agent using RUCAM (see Table e56-2)
- The severity of the reaction
- Determine through consultation with the medical team and patient if a rechallenge with the probable causative agent is worthwhile

Plan*

- Drug therapy regimen to replace the drug or herb that must be discontinued
- Monitoring parameters to determine liver recovery, note that there will be short-term and long-term needs
- Patient education on drug or herbs to avoid in the future and any long-term issues that may need to be addressed with future drug therapy utilizing hepatically cleared agents

Implement*

- Discontinue probable drug and schedule initiation of replacement therapy
- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Resolution of signs and symptoms (jaundice, abdominal distention, liver enzymes elevation)
- Recovery of stamina and strength (often takes months)
- Evaluation replacement drug regimen for safety and efficacy

**Collaborate with the patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Because it is important to compare cases of liver injury across the world and across time, we use common designations for each type of liver injury. You can see a concise and commonly accepted approach in LiverTox which is part of the NCBI Bookshelf at https://www.ncbi.nlm.nih.gov/books/NBK547852/. Look under “Phenotypes.”

It is important to stratify the likelihood that a particular drug has caused this liver injury and decide what are likely candidates. The text provides the RUCAM scoring system and references some supporting literature for its use. The authors of LiverTox at https://www.ncbi.nlm.nih.gov/books/NBK547852/ have a less favorable view of RUCAM and provide several other choices for you to consider, you can score the above case and see how each approach differs. Look under “Causality.”

INTRODUCTION

The range of drugs associated with adverse reactions involving the liver is extensive, but in clinical practice is dominated by alcohol, antibiotics, antiseizure medications, and acetaminophen.[1] Complementary and herbal medicines also contribute disproportionately to this disease burden. Drug-induced liver injury (DILI) is a potentially fatal, often debilitating outcome of drug treatment. DILI is responsible for 11% to 13% of all cases of acute liver failure in the United States.[1,2]

Drug-induced liver injury accounts for as much as 20% of acute liver failure in pediatric populations and a similar percentage of adults with acute liver failure.[3] In approximately 75% of these cases, liver transplantation is ultimately required for patient survival.[4] Of patients who required liver transplantation according to the United Network for Organ Sharing, acetaminophen, isoniazid, antiepileptics, and antibiotics collectively account for just over 60% of cases.[5]

The liver's function affects every other organ system in the body; it in turn is exposed to every substance absorbed from the gut and every injected substance that enters the bloodstream.

MECHANISMS OF DRUG-INDUCED LIVER INJURY

Stimulation of Autoimmunity

Autoimmune injuries involve antibody-mediated cytotoxicity or direct cellular toxicity.[6,7] This type of injury occurs when enzyme-drug complexes migrate to the cell surface and form neoantigens. The liver plays host to all of the cells that make up the innate immune response in the body along with Kupffer cells, which act as a type of macrophage, derived from the reticuloendothelial cells. These Kupffer cells sit in anticipation along the lumen of the liver sinusoids waiting for glycoproteins, substances coated with immunoglobulins or complement factors to present themselves.[8] The reticuloendothelial cells that create the porous frame around the hepatocytes are constantly monitoring and communicating via cytokines to stimulate or regulate an immune response.[8] Neoantigens also serve as targets for cytolytic attack by killer T cells, and others.[9] Halothane, sulfamethoxazole, carbamazepine, nevirapine, fluoroquinolones, and anti-tumor necrosis factor (TNF) alpha inhibitors are associated with autoimmune injuries.[2,10] Stimulation of autoimmunity is often associated with fulminant presentations.

Dantrolene, isoniazid, phenytoin, nitrofurantoin, trazodone, and methyldopa are associated with a type of autoimmune-mediated disease in the liver called *chronic active hepatitis.*[11,12] Patients experience periods of symptomatic hepatitis followed by periods of convalescence, only to repeat the experience months later. It is a progressive disease with a high mortality rate and is more common in females than males. Antinuclear antibodies (ANA) appear in most patients. These drugs appear to form anti-organelle antibodies.[13] The exact identification of a causative agent is sometimes difficult as diagnosis requires multiple episodes occurring long after exposure to the offending drug.

Idiosyncratic Reactions

Idiosyncratic drug-related hepatotoxicity is rare and usually occurs in a small proportion of individuals. These adverse reactions are often categorized into allergic and nonallergic reactions. Allergic reactions represent up to 37% of all idiosyncratic drug-induced liver injuries and are characterized by fever, rash, eosinophilia, and granulomas.[12] They are usually dose-related and have a short latency period (less than 1 month). On re-exposure to the offending agent, there is a rapid recurrence of hepatotoxicity. Minocycline, nitrofurantoin, phenytoin, amoxicillin-clavulanate, sulfamethoxazole-trimethoprim, angiotensin-converting enzyme inhibitors, and allopurinol can cause allergic reactions.[2,12,14]

③ Human leukocyte antigen (HLA) phenotypes mediate a patient's susceptibility and severity of inflammatory reactions in the liver. HLA type A*33:01 has been identified through genome-wide association studies with several drugs that have induced idiosyncratic reactions.[15] Additional HLA phenotypes exist that further increase the likelihood and severity of these reactions, which includes HLA type A*33:01; HLA type B*35:01, HLA type B*14:02, and HLA type C*08:021.[5,16] ③ HLA type B*5701 has separately been associated with reactions for flucloxacillin and abacavir.[17-20] Although not useful for management of the acutely ill patient, monocyte-derived, hepatocyte-like cell cultures can be used to confirm the culprit in an idiosyncratic reaction.[21,22] Amiodarone, isoniazid, and ketoconazole are associated with nonallergic drug-related hepatotoxicity.[14]

The nonallergic idiosyncratic reactions are devoid of the hypersensitivity features, usually have a long latency period (several months), and are not associated with rapid reinjury with rechallenge.[2] These patients often have normal liver function tests for 6 months or longer and then suddenly develop hepatotoxicity. Dependent on the medication, the incident can be independent of dose or dose related.

Disruption of Calcium Homeostasis and Cell Membrane Injury

Drug-induced damage to the cellular proteins that are involved with calcium homeostasis can lead to an influx of intracellular calcium that causes a decline in adenosine triphosphate levels and disruption of the actin fibril assembly.[22] The resulting impact on the cell is blebbing of the cell membrane, rupture, and cell lysis.[17] Lovastatin, venlafaxine, and phalloidin, which are the active components of mushrooms, impair calcium homeostasis.[7,23]

Cytochrome P450 Enzymes as Agents of Liver Damage

① ③ Most hepatocellular injuries involve the production of high-energy reactive metabolites by the CYP450 system. ① These reactive metabolites can form covalent bonds with transport proteins, enzymes, and nucleic acids. In the case of acute toxicity, these enzyme-drug complexes can cause cell injury or cell lysis.[22] The complexes that form with DNA can induce neoplasia. Acetaminophen, furosemide, and diclofenac become hepatotoxin through this mechanism.[7] Individual genetic differences can play a role in the significance of this process. Patients with a single nucleotide polymorphism (SNP) that codes for slow-reacting variants of CYP450 will react differently from those with an SNP that codes for very fast-reacting variants. These reactions will occur primarily in the smooth endoplasmic reticulum (SER) of the hepatocyte. Since the SER occupies a large portion of the cytoplasm of the hepatocyte, these reactions tend to be dispersed throughout the cell.[23]

Liver Transport Proteins and Liver Cell Communities as Agents of Liver Damage

③ As illustrated in Fig. e56-1, genetics and the innate roles of several proteins and cell types either accelerate or protect the liver from damage. Efflux membrane transport proteins such as organic anion transporting proteins 1B1, 1B3, and 2B1 actively pump drugs and other xenobiotics into the hepatocyte for processing and elimination from the body (Table e56-1, Fig. e56-1).[24-28] Canalicular membrane efflux transporters pump metabolites and some drugs into the bile canaliculus (Fig. e56-1). SNPs that code for various bile salt export pumps (BSEP), specifically variants of ATP-binding cassette transporters ABCB4, ABCB11, and ABCR3, are associated with rare congenital liver diseases and cholestasis during pregnancy.[29,30] These patients may have a higher risk for cholestatic liver injury. Cyclosporine A, sulindac, rifamycin, and glimepiride inhibit BSEP. Multi-drug and toxin extrusion exchanger 2 (MATE2) in the liver is important for excretion of cationic drugs such as metformin, oxaliplatin, acyclovir, and fexofenadine. There are several SNPs that are associated with modified MATE2 function.[29,30]

Figure e56-1

Regions and structures of importance for drug-induced liver injury. 1. cytoplasm; 2. biliary canaliculus; 3. liver sinusoids; 4. hepatic stellate cells; 5. sinusoidal endothelial cells; 6. Kupffer cells; A. smooth endoplasmic reticulum; B. rough endoplasmic reticulum; C. uptake transport membrane proteins; D. efflux transport membrane proteins.

TABLE e56-1

Important Transport Protein Families

Sinusoidal Membrane Uptake Transporters (remove drugs from blood)	
Organic Anion Transporting Polypeptides	1B1, 1B3, and 2B1 are the most important uptake proteins for drugs. Subjects with SNP (174Ala) showed lower transport efficiency for 1B1, resulting in less efficient uptake
Organic Cation Transporting Polypeptides	OCTP-1 is the hepatic form. Genetic SNP appears to be rare or rarely effect OCTP-1
Canalicular Membrane Efflux Transporters (pump metabolites into the bile)	
ATP-Binding Cassette; Transporter B1	Facilitates the biliary elimination of amphiphilic drugs
ATP-Binding Cassette; Transporter C2	Facilitates the biliary elimination of glutathione, glucuronide, and sulfate conjugates. SNP (C-24T) is associated with a risk of diclofenac hepatoxicity
ATP-Binding Cassette; Transporter G2	Facilitates the biliary elimination of methotrexate, pitavastatin, rosuvastatin, and most fluoroquinolones
Bile Salt Export Pumps	Facilitates the biliary elimination of bile acids along with pravastatin and vinblastine. Multiple SNPs exist; some result in rare congenital liver diseases. Cyclosporine A, sulindac, rifamycin, and glimepiride inhibit BSEP
Multi-Drug and Toxin Extrusion Exchanger 2	Facilitates the biliary elimination of metformin, cimetidine, oxaliplatin, acyclovir, and fexofenadine along with other cationic drugs. Multiple types and distributions of SNP have been identified, which modify transport rates
Sinusoidal/Basolateral Membrane Excretory Transporters (pump metabolites back out to the blood or into other hepatocytes)	
ATP-Binding Cassette; Transporter C3	Facilitates the excretion of glucuronide conjugates
ATP-Binding Cassette; Transporter C4	Facilitates the excretion of adefovir, ganciclovir, methotrexate, 6-mercaptopurin, and steroids
ATP-Binding Cassette; Transporter Cs	Upregulated in response to cirrhosis
Organic Solute Transporter Alpha/Beta	Facilitates the excretion of estrone; related compounds and bile acids

Data from References 27,28.

① Hepatic stellate cells (HSC) reside within the space of Disse (Fig. e56-1).[29] They are important for the storage and processing of lipids and vitamin A through the production of cytoglobin.[31] When activated by cytokines from the sinusoidal endothelial and Kupffer cells, the HSC transform into damage repair cells.[32] However, when there is extensive damage, HSC will significantly reduce the amount of cytoglobin they produce. This loss of cytoglobin is associated with an acceleration of fibrosis and neoplastic responses to the damage.[31] HSC show some degree of genetic diversity along with the effects of aging particularly in pursuing their repair roles.[31-33,35,36]

The Kupffer cells are liver-centric specialized monocytes. ① They phagocytize foreign materials in the blood from the central vein and mediate inflammatory reactions. Large-scale activation of the Kupffer cells is the first step toward hepatitis.[29,30,33,34]

Stimulation of Apoptosis

Apoptosis represents a distinct pattern of cell lysis that is characterized by cell shrinkage and fragmentation of nuclear chromatin. Apoptotic pathways are triggered by interactions between death ligands tumor necrosis factor and Fas ligand and death receptors tumor necrosis factor receptor 1 and Fas receptor. These interactions activate caspases, which cleave cellular proteins and eventually lead to cell death.[37]

Mitochondrial Injury

Drugs that impair mitochondrial structure, function, or DNA synthesis can disrupt β-oxidation of lipids and oxidative energy production within the hepatocyte.[21,38] In acute disease, prolonged interruption of β-oxidation leads to microvesicular steatosis, whereas in chronic disease, macrovesicular disease is present.[37] Severe damage to the mitochondria eventually leads to hepatic failure and death. Aspirin, valproic acid, and tetracycline cause mitochondrial injury by inhibiting β-oxidation and amiodarone via disruption of oxidative phosphorylation.[21]

Liver Neoplastic Disease

Carcinoma- and sarcoma-like lesions have developed following drug therapy. Fortunately, hepatic tumors associated with drug therapy are usually benign, remitting when drug therapy is discontinued. Usually, these lesions are associated with long-term exposure to the offending agent.[39,40] Androgens, estrogens, and other hormonal-related agents are the most frequently associated causes of neoplastic disease. The model for drug-induced hepatic cancer is polyvinyl chloride exposure. Used in the production of many types of plastic products, polyvinyl chloride induces angiosarcoma in exposed workers in as few as 3 years of a high-quality exposure.[4,39,41]

ASSESSMENT: THE PATTERN OF LIVER ENZYME CHANGES

②⑤⑤⑤ Drug-induced liver injury is categorized in two ways. The most common way to categorize DILI is by the pattern of liver enzyme changes. Through this approach two questions can be answered: (1) Is this liver injury? and (2) What type of liver injury is likely emerging? In severe cases a liver biopsy is used to categorize DILI by the pattern of histological changes. For the majority of DILI cases, the first indicator of injury is the elevation of the enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (Alk Phos) and total bilirubin. Additional liver enzymes and other laboratory findings that will be useful include 5′-nucleotidase (5-NT), γ-glutamyltransferase (GGTP), lactic dehydrogenase (LDH), and antismooth muscle antibodies (ASMA). Liver kidney microsomal auto-antibodies (LKM-1) are indicative of autoimmune hepatitis. Micro-RNA (mRNA) values are elevated in steatosis and ballooning inflammation. These laboratory findings break out into three primary categories of DILI: (1) hepatocellular damage, (2) cholestatic damage, and (3) mixed hepatocellular cholestatic damage.

Hepatocellular Injury

②⑤ Hepatocellular injury is characterized by significant elevations in the serum aminotransferases, which usually precede elevations in total bilirubin levels in serum and alkaline phosphatase levels.[42] Hy's law defines hepatocellular injury as an increase in ALT that is at least three times above the upper limit of normal (UNL) with concurrent rise in TBL to a point at least 2 UNL without a significant rise in the Alk Phos (Table e56-2).[43,44] The US Food and Drug Administration (FDA) along with the Council for International Medical Sciences recommend evaluating the ratio of the ALT to the Alk Phos as well. Hepatocellular injury then becomes defined as ALT > 3 UNL plus TBL > 2 UNL plus R = (Measured ALT/Upper Normal Limit of ALT) ÷ (Measured Alk Phos/Upper Normal Limit of Alk Phos), where R > 5.[2,43,44]

TABLE e56-2

Roussel Uclaf Causality Assessment Method (RUCAM)

Criteria	Result	Score	Result	Score
Timing (days) from…				
…start of therapy	5-90	+2	<5 or >90	+1
… or cessation of therapy (except slowly metabolized drugs)			≥30	+1
Result of unintentional rechallenge of drug/herb alone	Alk Phos > 2XN	+3	Alk Phos ≤ Normal	−2
Result of unintentional rechallenge drugs/herbs given	Alk Phos > 2XN	+1	Alk Phos ≤ Normal	0
Previous reports of this drug and this reaction in…	Product labeling	+2	Published literature	+1
Concurrent hepatoxic drug/herb?	No	0		
If yes, Is hepatoxic drug/herb timing…	Consistent	−2	Inconsistent	0
Concurrent drug/herb more likely?	Positive Rechallenge	−3	Validated Test	−3
Risk Factor: Drinks/day Alcohol > 2 (female) > 3 (male)	Yes	+1	No	0
Risk Factor: Pregnant?	Yes	+1	No	0
Risk Factor: Age > 55 years old	Yes	+1	No	0
Alternatives to Rule Out				
Group I Alternative: Hepatitis A Virus via + Anti-HAV-IgM				
Group I Alternative: Hepatitis B Virus via + Anti-HBV-IgM or + HBV-DNA				
Group I Alternative: Hepatitis C Virus via + Anti-HCV-IgM or + HCV-RNA				
Group I Alternative: Hepatitis E Virus via + Anti-HEV-IgM, + Anti-HEV-IgG or + HEV-RNA				
Group I Alternative: Other positive test for other liver diseases or disorders, such as Hepatobiliary Sonography, Color Doppler Sonography, Endosonography, Liver CT Scan, Liver MRI				
Group I Alternative: Diagnosis of Alcoholism with elevated AST of ALT > 2				
Group I Alternative: Recent hypotensive history (particularly with underlying heart disease)				
Group II Alternatives: Autoimmune Hepatitis, Chronic Viral Hepatitis, Biliary or Sclerosing Cholangitis				
Group II Alternatives: Complications of Sepsis, Metastatic Malignancy, Genetic Liver Diseases				
Group II Alternatives: Positive Test for Infection Cytomegaly, Epstein-Bar, Herpes Simplex, Varicella-Zoster Viruses				
All Alternatives Ruled Out	Groups I and II	+2	Group I only	+1

Some Alternatives Ruled Out	5-6 of Group I	0	<5 of Group I	−2
An Alternative Cause is…	Highly Likely	−3	Somewhat Likely	0

Total Score ≤ 0 – means the drug or herb is not a likely cause; ≤ 2 – means it is unlikely to be the cause; ≤ 5 – means the drug or herb possibly may have caused this reaction; ≤ 8 - means the drug or herb is a probable cause of the reactions and > 8 – means the drug or herb is highly probable to be the cause. (2×N = Two Times the Normal Upper Limit)

Data from Reference 43.

Most hepatocellular injuries occur within 1 year of starting drug therapy. Hepatocellular injury can lead to fulminant hepatitis with a corresponding 20% survival rate with supportive care.[37] For those patients who present with the combination of hepatocellular injury and jaundice, there is a 10% mortality rate.[40] Acarbose, allopurinol, fluoxetine, and *losartan* are capable of causing hepatocellular injury.[42]

⑤ ⑤ Autoimmune hepatocellular injury is often accompanied by fever and elevations in ANA, ASMA, LKM-1, and gamma globulins. Typically, this type of DILI is more rapid in onset (less than 2 months from start of therapy) and fulminant.[45] If identified early, autoimmune hepatocellular injury may respond to high-dose glucocorticoid treatment. This treatment must be carefully targeted, since glucocorticoid treatment can worsen underlying fatty liver disease.[20]

Hepatocellular injuries can be further subdivided by specific histologic patterns and clinical presentations. Centrolobular necrosis, steatohepatitis (steatonecrosis), phospholipidosis, and generalized hepatocellular necrosis are each identifiable by biopsy results.[46]

Cholestatic Injury

② ⑥ Cholestatic disease is more often seen in patients over the age of 60 and is slightly more common in males.[9] In cholestatic disease, disturbance of the subcellular actin filaments around the canaliculi prevents the movement of bile through the canalicular system.[21] Mutations in hepatic transporter genes can result in slower function prior to toxin exposure.[47] The inability of the liver to remove bile causes intrahepatic accumulation of toxins and waste products.[21,47]

⑤ Alkaline phosphatase is the dominant enzyme with cholestatic injury.[3] Cholestatic injury is defined by an Alk Phos > 3 UNL plus TBL > UNL plus and R ≤ 2. Erythromycin-associated DILI is the prototype for this injury, along with amoxicillin–clavulanic acid, and carbamazepine.[37] An IV form of vitamin E, α-tocopheryl acetate, causes cholestatic jaundice, primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (more than 10%) and the mortality even higher (more than 50%).[48]

Cholestatic injury is also known as cholestatic jaundice or cholestasis and can be further classified by the area of the bile canalicular or ductal system that is impaired. Canalicular cholestasis is often associated with long-term, high-dose estrogen therapy. These patients are often asymptomatic and present with mild-to-moderate elevations of serum bilirubin.[49]

A subtype of cholestatic injury, often associated with antibiotic usage, is “vanishing bile duct syndrome” occurring in 7% of all cases reported to the Drug Induced Liver Injury Network (DILI-Net) between 2004 and 2014.[50] The finding on biopsy of bile duct loss appears to be associated with progression to severe cholestatic disease in most cases, even if the loss is minimal or early.[51]

Mixed Hepatocellular and Cholestatic Injury

② ⑤ This pattern, as the name implies, is the result of both hepatocytes and bile canalicular cells bearing damage at approximately the same time.

ASSESSMENT: THE PATTERN OF HISTOLOGIC CHANGES

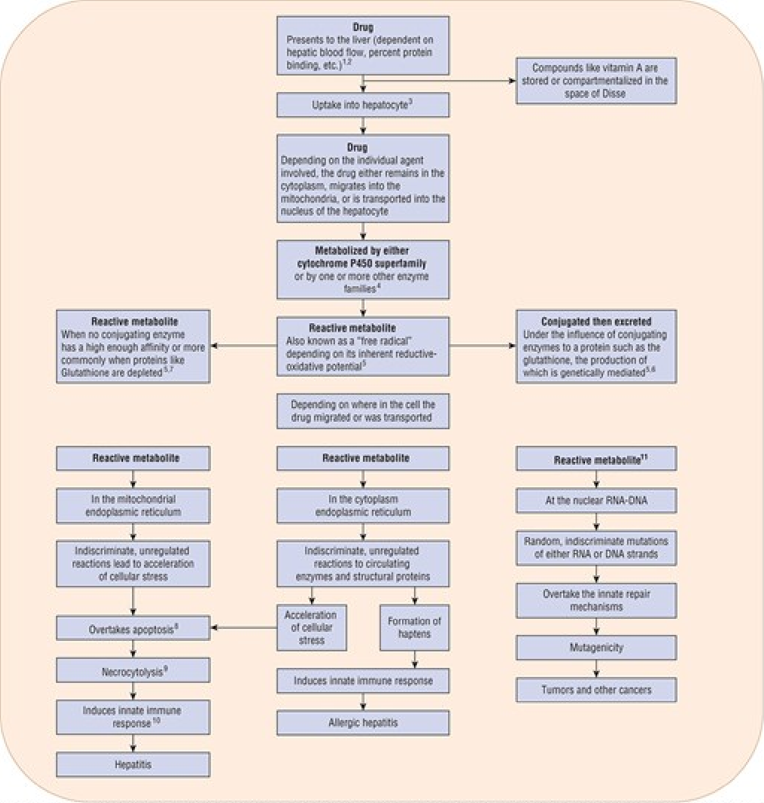
Samples of tissue obtained through biopsy are the best and most reliable identification technique in determining the impact of DILI. Evermore sophisticated magnetic resonance imaging, CT-scans, and ultrasonography are slowly replacing liver biopsy as the first choice in determining the pattern of histological changes clinically. Important anatomical features of the liver are illustrated in Fig. e56-1.

Centrilobular Necrosis

② ① Centrilobular necrosis describes a pattern of cell damage that originates in the hepatocytes located nearest the central vein of the liver. Centrolobular necrosis is often the result of the production of a toxic metabolite (Fig. e56-2). The damage spreads outward from the middle of a lobe of the liver.

Figure e56-2

A general diagram of biotransformation. (1) Hepatic blood flow, which changes proportionately with changes in cardiac output, delivers the drug to the liver. (2) Protein binding is most affected by nutritional status and competing drugs. (3) The drug is actively transported into the hepatocyte by the organic anion transport pump, a transmembrane protein. (4) The metabolite (drug) interacts with one of a number of enzymes, the most common being CYP2C9, CYP2C19, CYP2D6, and CYP3A4. This family of enzymes is regulated by the complementary DNA xenobiotic receptor. The xenobiotic receptor is in turn upregulated by other drugs, changes in cholesterol catabolism, and bile acids. The immediate result of the action of these phase I enzymes is the production of a reactive metabolite. (5) The unstable metabolite then reacts with glucuronidase, various transferases, or hydroxylases to form a conjugated metabolite. The efficacy of these enzymes is affected by the patient's nutritional state and genetic polymorphism, leading to variations in individual risk for toxicity. (6) The conjugated metabolite is removed from the hepatocyte by the canalicular membrane export pump, one of a large family of membrane proteins (other members of this family pump conjugated metabolites back into the blood for excretion by the kidney). These proteins are subject to genetic polymorphism as well, again leading to some patients having an increased risk for toxicity. (7) If unable to form a conjugate, the unstable metabolite can participate in oxidative reactions that damage lipids, proteins, or even DNA. (8) The normal process of cellular aging, death, and reabsorption by surrounding cells. (9) Widespread, rapid cellular death with the creation of multiple antigens. (10) Activation of Kupffer cells, killing cells, B cells, and other T cells with the associated production of inflammatory cytokines, the relative numbers of which and the innate activity of each are mediated by genetic polymorphism. (11) Drugs or active metabolites that are transported or diffuse into the mitochondria or the nucleus can damage DNA leading to mutagenicity and ultimately hepatic cancers.



Drug
Presents to the liver (dependent on hepatic blood flow, percent protein binding, etc.)1,2
Compounds like vitamin A are stored or compartmentalized in the space of Disse
Uptake into hepatocyte3
Drug
Depending on the individual agent involved, the drug either remains in the cytoplasm, migrates into the mitochondria, or is transported into the nucleus of the hepatocyte
Metabolized by either cytochrome P450 superfamily
or by one or more other enzyme families4
Reactive metabolite
When no conjugating enzyme has a high enough affinity or more commonly when proteins like Glutathione are depleted5,7
Reactive metabolite
Also known as a "free radical" depending on its inherent reductive-oxidative potential5
Conjugated then excreted
Under the influence of conjugating enzymes to a protein such as the glutathione, the production of which is genetically mediated5,6
Depending on where in the cell the drug migrated or was transported
Reactive metabolite
In the mitochondrial endoplasmic reticulum
Indiscriminate, unregulated reactions lead to acceleration of cellular stress
Overtakes apoptosis8
Necrocytolysis9
Induces innate immune response10
Hepatitis
Reactive metabolite
In the cytoplasm endoplasmic reticulum
Indiscriminate, unregulated reactions to circulating enzymes and structural proteins
Acceleration of cellular stress
Formation of haptens
Induces innate immune response
Allergic hepatitis
Reactive metabolite11
At the nuclear RNA-DNA
Random, indiscriminate mutations of either RNA or DNA strands
Overtake the innate repair mechanisms
Mutagenicity
Tumors and other cancers

Patients suffering from centrolobular necrosis tend to present in one of two ways, depending on the extent of necrosis. Mild drug reactions, involving only small amounts of parenchymal liver tissue, may be detected as asymptomatic elevations in the serum aminotransferases. If the reaction is diagnosed at this stage, most of these patients will recover with minimal cirrhosis and thus minimal chronic liver impairment. More severe forms of centrolobular necrosis are accompanied by nausea, vomiting, upper abdominal pain, and jaundice.[10,52]

These reactions are predictable, often dose-related effects in the liver caused by specific agents. When taken in overdose, acetaminophen becomes bioactivated to a toxic intermediate known as *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI is highly reactive, with a high affinity for sulfhydryl groups. The tripeptide glutathione provides a ready source of available sulfhydryl groups within the hepatocyte. When the liver's glutathione stores are depleted and there are no longer sulfhydryl groups available to detoxify this metabolite, it begins to react directly with the hepatocyte. The depletion of glutathione changes the mitochondrial oxidized to reduced glutathione ratio resulting in catastrophic shifts in mitochondrial function, accelerating cell necrocytolysis.[53] Continuing mitochondrial damage leading to fragmentation of mitochondrial DNA leads directly to necrosis.[54] Replenishing the liver's sulfhydryl capacity through the administration of *N*-acetylcysteine early after ingestion of the overdose halts this process.[48] During the first hours after ingestion, some patients report mild symptoms of nausea and vomiting, but no elevations of the commonly measured liver enzymes are seen. Serum elevations in the liver enzymes begin 40 to 50 hours after ingestion.[55] Circulating cell-free mRNA (liver-specific mR-122) begins to rise after only 1 hour in rat models of acetaminophen overdose. This may lead the way to earlier detection of many drug-induced liver injuries in the future.[56]

Nonalcoholic Steatohepatitis

② Nonalcoholic steatohepatitis (NASH), also known as steatohepatitis and steatonecrosis, results from the accumulation of fatty acids in the hepatocyte. In the preacute stages, this is known as nonalcoholic fatty liver disease (NAFLD). Drugs or their metabolites that cause NAFLD do so by affecting fatty-acid esterification and oxidation rates within the mitochondria of the hepatocyte (see Fig. e56-2). Hepatic vesicles become engorged with fatty acids, eventually disrupting hepatocyte homeostasis. In patients with diabetes, various dyslipidemias, and even hypertension, the de novo production of free fatty acids from excess circulating carbohydrates accelerates this process of accumulation. The liver biopsy is marked by infiltration of polymorphonuclear leukocytes, degeneration of the hepatocytes, and Mallory bodies.[57]

Alcohol is the drug that most commonly produces steatonecrotic changes in the liver. When alcohol is converted into acetaldehyde, the synthesis of fatty acids is increased.[58,59] The hepatocyte can become completely engorged with microvesicular fat, resulting in alcoholic fatty liver. Metabolically this type of de novo free fatty acid synthesis depletes NADPH in favor of NADP+ and reduces the hepatocytes' ability to respond to stress, bypassing normal apoptosis, and increasing the rate of necrocytolysis. Because of the pervasive nature it begins to react directly with the hepatocyte (see Fig. e38-1). It is commonly referred to separately as alcoholic liver disease (analogous to NAFLD) and alcoholic hepatitis (analogous to NASH).

In NAFLD, the same endpoint is often achieved through oxidation of lipid peroxidases.[60] If the offending agent is withdrawn before significant numbers of hepatocytes become necrotic, the process is completely reversible without long-term sequelae. If not, then ever-increasing rates of necrocytolysis will induce an innate immune response and result in hepatitis. NAFLD is a common result of certain subtypes of type 2 diabetes mellitus. Here the cause is related to aberrant carbohydrate and liver metabolic rates and is strongly associated with insulin resistance.

③ Tetracycline produces NAFLD and NASH.[56] The lesions are characterized by large vesicles of fat found diffused throughout the liver. The development of this reaction is related to the high concentrations achieved when tetracycline is given IV and in doses greater than 1.5 g/day. Sodium valproate also can produce steatonecrosis through the process of bioactivation. Cytochrome P450 converts valproate to Δ-4-valproic acid, a potent inducer of microvesicular fat accumulation.[61,62]

Patients experiencing steatohepatitis may present with abdominal fullness or pain as their only complaint. Patients with more severe steatonecrosis will present with all the symptoms characteristic of alcoholic hepatitis such as nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue.

Phospholipidosis

② ⑥ Phospholipidosis is the accumulation of phospholipids instead of fatty acids. The phospholipids usually engorge the lysosomal bodies of the hepatocyte.[58] Amiodarone is associated with this reaction. Patients treated with amiodarone who develop overt hepatic disease tend to have received higher doses of the drug. These patients also have higher amiodarone-to-*N*-desethylamiodarone ratios, indicating a greater accumulation of the parent compound. Amiodarone and its major metabolite *N*-desethylamiodarone remain stored in the stellate cells (Fig. e56-1) of patients for months after therapy is stopped. Usually the phospholipidosis develops in patients treated for more than 1 year. The patient can present with either elevated aminotransferases or hepatomegaly; jaundice is rare.[13,57]

Generalized Hepatocellular Necrosis

② Generalized hepatocellular necrosis mimics the changes associated with the more common viral hepatitis. The onset of symptoms is usually delayed as much as a week or more after exposure to toxin. Bioactivation is often important for toxic hepatitis to develop. Many drugs that are associated with toxic hepatitis produce metabolites that are not inherently toxic to the liver. Instead, they bind with proteins to create haptens, which serve as neoantigens and induce the innate immune response (see Fig. e56-1).[63,64]

③ The rate of bioactivation can vary between individuals.[65,66] The superfamily of CYP450 enzymes metabolizes lipophilic substrates that are actively pumped into the hepatocyte by an organic anion (or cation) transporting protein. The CYP450 subspecies 2C9, 2C19, 2D6, 3A4, and 4F8 are regulated by the highly inducible xenobiotic receptor on DNA. The receptor is found in the liver, and to a lesser extent in the cells lining the intestinal tract, and is responsible for cholesterol catabolism and bile acid homeostasis. The activity of this receptor is subject to genetic polymorphism. This results in a wide variation in the sensitivity of the population to hepatic damage.[67]

③ The long-term administration of isoniazid can lead to hepatic dysfunction in 10% to 20% of those receiving the drug. Yet severe toxic hepatitis develops in only 1% or less of this population.[68] The *N*-acetyltransferase-2 (NAT2) genotype appears to play a role in determining a patient's relative risk. Seventy percent of patients who developed elevated liver enzymes (defined as at least 2.5 times upper normal) or jaundice were slow acetylators.[69] Isoniazid is metabolized by several pathways, acetylation being the major pathway. It is acetylated to acetylisoniazid, which, in turn, is hydrolyzed to acetylhydrazine.[70] Acetylhydrazine, and to a lesser extent the acetylisoniazid, is directly toxic to the cellular proteins in the hepatocyte, but rapid acetylators detoxify acetylhydrazine rapidly, converting it to diacetylhydrazine (a nontoxic metabolite). The rate and efficiency of this reaction sequence ultimately determines if hepatocellular damage will ensue.

③ ⑥ ⑥ Isoniazid simultaneously is an example of the potential predictability of DILI based on SNP and a lesson in the limitations of our current understanding. There are definite links to NAT2 genotype and toxicity.[71] In particular the polymorphic forms of NAT2 *5, NAT2 *6, NAT2 *7, and NAT2 *14 encode for slow acetylation.[72] The risk for this reaction is also influenced heavily by the age, which is a stronger risk factor than phenotype.[68,69,71] Females, patients with low BMI, patients diagnosed with alcohol misuse, AIDS, hepatitis B, hepatitis C, and those with previous hepatic injuries are reported more often to have suffered injury than the general population.[71,72] In one prospective series focused on DILI, cases involving isoniazid had a median onset at 6 months of therapy with around 30% of isoniazid-induced liver disease clustered between 6 and 8 months.[8]

Ketoconazole produces generalized hepatocellular necrosis or milder forms of hepatic dysfunction in up to 2% of patients treated for fungal infections. The onset is usually early in therapy. In immunocompromised patients in whom ketoconazole is used, special care should be taken to watch for changes in liver function.[73]

Toxic Cirrhosis or Fibrosis

② The scarring effect of hepatitis in the liver leads to the development of cirrhosis through a process known as fibrosis. Some drugs tend to cause such a mild case of hepatitis that it may not be detected. Mild hepatitis can be easily mistaken for a more routine generalized viral infection. If the offending drug or agent is not discontinued, this damage will continue to progress. The patient eventually presents not with hepatitis, but with cirrhosis. The loss of cytoglobin, a stellate cell-specific protein complex, may mark the beginnings of this process.[33]

⑥ Methotrexate causes periportal fibrosis in most patients who experience hepatotoxicity. The lesion results from the action of a bioactivated metabolite produced by CYP450.[74] This process occurs most commonly in patients treated for psoriasis and arthritis. Periodic liver biopsies have a low yield in patients without other risk factors for liver disease, and should be reserved for select high-risk patients.[53,75] Vitamin A is normally stored in liver cells, and causes significant hypertrophy and fibrosis when taken for long periods in high doses. Hepatomegaly is a common finding, along with ascites and portal hypertension. In patients with vitamin A toxicity, gingivitis and dry skin are also very common. This is accelerated by ethanol, which competes with retinol for aldehyde dehydrogenase.[58]

Liver Vascular Disorders

② Focal lesions in hepatic venules, sinusoids, and portal veins occur with various drugs. Commonly associated drugs include the cytotoxic agents used to treat cancer, the pyrrolizidine alkaloids, and the sex hormones. A centralized necrosis often follows the vasculitis and can result in cirrhosis. Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) are associated with venoocclusive disease. The exact incidence is rare and may be dose related.[57] Peliosis hepatitis is a rare type of hepatic vascular lesion that can be seen as both an acute and a chronic disease. The liver develops large, blood-filled cavities within the parenchyma. Rupture of the lacunae can lead to severe peritoneal hemorrhage. Peliosis hepatitis is associated with androgens, estrogens, tamoxifen, azathioprine, and danazol. Androgens with a methyl alkylation at the 17-carbon position of the testosterone structure are the most frequently reported agents that cause peliosis hepatitis, usually after at least 6 months of therapy.[76]

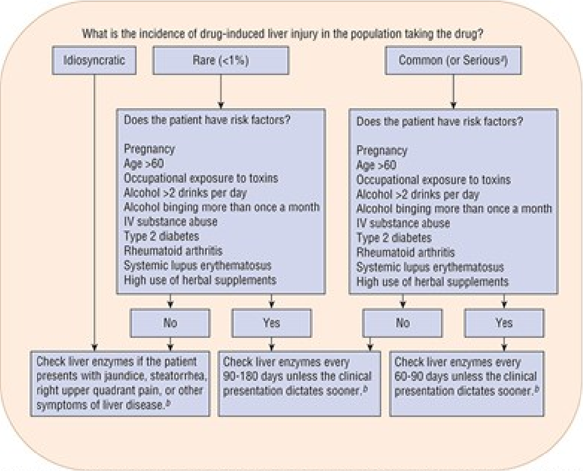
ASSESSMENT: DETERMINING THE MEDICATION-RELATED PROBLEM

④ It is important to document the pattern of liver enzyme changes, the pattern of histologic changes if known to assess the medication-related problem. Key information also comes from the patient's history. Confirming DILI requires the exclusion of common causes of liver injury, the timing of drug exposure to injury onset, along with supporting laboratory and clinical features. ④ Causality assessment tools include the Roussel Uclaf Causality Assessment Method (RUCAM), Clinical Diagnostic Scale, and Digestive Disease Week Japan system.[44] RUCAM was the first causality assessment method that defined criteria of liver injury by using liver test thresholds based upon multiples of upper limits of normal of liver function tests as a diagnostic criterion.[2,3,44]

⑥ A patient's history of drug use is essential to consider (Fig. e56-3).[72-75] Drugs used for recreational purposes must not be overlooked. Cocaine has been directly linked to liver disease.[80,81] Methylenedioxymethamphetamine (MDMA or Ecstasy) has induced deadly fulminant hepatitis as have various combinations of the so-called synthetic marijuana or Spice.[82,83] The more pervasive but harder to detect impact of street drugs on the incidence of hepatic disease is the concomitant injection or ingestion of adulterants. Talc, heavy metals, and various solvents are used. Many of these adulterants are either directly toxic or serve to enhance the toxicity of the drug (see Table e56-2).

Figure e56-3

An approach to determining a drug-monitoring plan for patients prescribed potentially hepatotoxic drugs. Notes: ^{a}Serious reactions would include those that occur rarely but have a very high morbidity or mortality rate. Common reactions would be reported in 1% or more patients taking the drug. ^{b}Concomitant therapy with another hepatotoxic drug will elevate the potential risk of a reaction and should lead to more frequent monitoring.



What is the incidence of drug-induced liver injury in the population taking the drug?
Idiosyncratic
Rare (<1%)
Common (or Serious^a)
Does the patient have risk factors?
Pregnancy
Age >60
Occupational exposure to toxins
Alcohol >2 drinks per day
Alcohol binging more than once a month
IV substance abuse
Type 2 diabetes
Rheumatoid arthritis
Systemic lupus erythematosus
High use of herbal supplements
Does the patient have risk factors?
Pregnancy
Age >60
Occupational exposure to toxins
Alcohol >2 drinks per day
Alcohol binging more than once a month
IV substance abuse
Type 2 diabetes
Rheumatoid arthritis
Systemic lupus erythematosus
High use of herbal supplements
No
Yes
No
Yes
Check liver enzymes if the patient presents with jaundice, steatorrhea, right upper quadrant pain, or other symptoms of liver disease.^{b}
Check liver enzymes every 90-180 days unless the clinical presentation dictates sooner.^{b}
Check liver enzymes every 60-90 days unless the clinical presentation dictates sooner.^{b}

④ It is also important to determine nondrug hepatic disease risk from occupational or environmental exposure. Arsenic is known to induce both acute and chronic hepatic reactions.[77] Even if exposure to an environmental toxin does not produce a hepatic reaction, it may predispose a patient to a hepatic reaction when a drug is added.[77-80] Table e56-3 lists some of the more common hepatic toxins found in occupational or environmental exposures that can add to the risk for developing a hepatic lesion.[79] Immune-mediated chronic liver diseases can often be tracked to geographic clusters that correspond to known toxic waste sites around the world.[84]

TABLE e56-3

Environmental Hepatotoxins and Associated Occupations at Risk for Exposure

Hepatotoxin	Associated Occupations at Risk for Exposure
Arsenic	Chemical plant, agricultural workers
Carbon tetrachloride	Chemical plant workers, laboratory technicians
Copper	Plumbers, sculpture artists, foundry workers
Dimethylformamide	Chemical plant workers, laboratory technicians
2,4-Dichlorophenoxyacetic acid	Horticulturists
Fluorine	Chemical plant workers, laboratory technicians
Toluene	Chemical plant, agricultural workers, laboratory tech
Trichloroethylene	Printers, dye workers, cleaners, laboratory technicians
Vinyl chloride	Plastics plant workers; also found as a river pollutant

④ ⑥ The history of a person's use of alternative medicines must be solicited. As traditional medicine usage is commonplace, herbal remedies and other traditional medicines accounted for 14 of 132 cases of DILI.[8] Comfrey tea is a common cause of hepatocellular damage. The Chinese remedy *jinbuhuan*, or the more elegantly presented chaparral capsules containing grease wood leaves, may occasionally cause severe disability or death from fulminant hepatic failure.[80] Pennyroyal oil, margosa oil (also *Neem Ka Tel* in India), and clove oil cause a dose-related hepatotoxicity.[85]

Patients with liver dysfunction are typically unable to identify a specific component in the dietary supplement being consumed. In a report covering 132 cases of herbal or supplement-related liver injury reported to the DILI-Net (https://dilin.org); 45 cases were related or caused by body building agents, likely an anabolic steroid in the supplement. Weight loss products were the next most frequently reported agents.[86] Products for depression, sexual performance, gastrointestinal upset, immune support, and joint care often combined with Chinese herbs made up another third of the reports.[86]

④ ④ The nutritional status of a patient can be as important to the development of a DILI as the hepatotoxin itself.[77-80] Patients who are malnourished because of illness or long-term alcohol misuse make up the most highest risk group.[87] Low serum levels of vitamins E and C along with lutein and the α- and β-carotenes are associated with asymptomatic elevations in transaminases. High serum iron, transferrin, and selenium levels are also associated with asymptomatic elevations of transaminases.[88]

When the drug in question is stopped the patient should be closely observed. It is also important to keep in mind that most elevations in liver enzymes will not be associated with a drug. In patients admitted to a hospital in the United Kingdom with elevated liver aminotransferases, only 9% of cases involved a drug other than alcohol as the possible cause.[13] In all cases of patients with elevated liver enzymes, titers of serum antibodies to hepatitis A, B, and C should be determined. Even in cases in which the drug is absolutely targeted as the cause, viral hepatitis may be a complication.[77-80]

ASSESSMENT: SEVERITY OF THE MEDICATION-RELATED PROBLEM

⑤ ⑤ Serum bilirubin concentration is a sensitive indicator of most hepatic lesions and has significant prognostic value. High peak bilirubin concentrations are associated with poor survival (Table e56-4). Other important findings that indicate poor survival are a peak prothrombin time greater than 40 seconds, elevated serum creatinine, and low arterial pH. The presence of encephalopathy or prolonged jaundice are not good signs for the survival of the patient and are strong indicators for transplantation.[89]

TABLE e56-4

Relative Patterns of Hepatic Enzyme Elevation versus Type of Hepatic Lesion

Enzyme	Abbreviations	Necrotic	Cholestatic	Chronic
Alkaline phosphatase	Alk Phos, AP	↑	↑↑↑	↑
5′-Nucleotidase	5-NC, 5NC	↑	↑↑↑	↑
γ-Glutamyltransferase	GGT, GGTP	↑	↑↑↑	↑↑
Aspartate aminotransferase	AST, SGOT	↑↑↑	↑	↑↑
Alanine aminotransferase	ALT, SGPT	↑↑↑	↑	↑↑
Lactate dehydrogenase	LDH	↑↑↑	↑	↑

Bilirubin concentrations and serum enzyme elevations give a static picture of the liver's condition and are not good indicators of hepatic function. Serum protein (albumin or transferrin) measurement can be used to assess hepatic function. As hepatic function decreases, serum protein concentrations decrease. Overhydration and starvation can also decrease serum protein concentrations. Albumin levels less than 2.8 g/dL (28 g/L) were associated with significant mortality following the onset of DILI.[90]

Elevations in blood monocyte counts appear to occur early and dramatically in acute hepatic injuries evolving into hepatitis.[37] Changes in the prothrombin time as reported as the international normalized ratio (INR) often occur earlier than the changes in albumin or transferrin. INR is a good predictor of liver function in acute liver failure.[91] The response of the INR to the administration of 10 mg of parenteral vitamin K has been used to differentiate between hepatic and extrahepatic disease.[91]

Novel Biomarkers for Drug-Induced Liver Injury

Because liver enzymes are released into circulation following most hepatocyte damage they do not provide insight into the mechanism of the underlying injury.[92,93] ⑤ Some of the novel biomarkers that may allow early detection and insight into underlying mechanisms include sorbitol dehydrogenase (SDH), micro-RNA 122, glutamate dehydrogenase (GLDH), cytokeratin 18 (CK 18), and high mobility group box 1 protein (HMGB1).[92,94]

SDH has been studied in various forms of liver injury and shows promise in the early detection of DILI.[93] The new biomarkers, micro-RNA 122, CK18, and HMGB1 are potentially useful in DILI as prognostic makers.[92,95] Likewise, GLDH, CK18, and HMGB1 have potential as mechanistic biomarkers. Elevated levels of serum GLDH are indicative of mitochondrial dysfunction and loss of mitochondrial integrity. The Apoptic Index, which is a measure of the ratio of CK18 to ccK18 levels in the serum, estimates the contribution of apoptosis and necrosis in the face of liver injury. The HMGB1 is also a marker of tissue necrosis and its acetylated form is a marker of activation of the innate immune system.[92,94]

In cases where either the cause or the severity of a liver injury is still in question, consultation with LiverTox is suggested. LiverTox (https://livertox.nih.gov/) provides information about drug-induced liver injury caused by drugs, herbals, and supplements. LiverTox also provides guidance on the diagnosis and management of DILI.

Documentation of Liver Injury

Once liver injury from a drug is diagnosed, it is important to share that information with other healthcare practitioners. Liver injury that is new or poorly established from a drug or herbal product should be reported to the FDA through MedWatch (https://www.fda.gov/safety/medwatch/default.htm).[96] For any severe drug-induced liver injury, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) has established the Drug-Induced Liver Injury DILI-Net at http://www.dilin.org/ to collect and analyze cases of severe liver injury caused by drugs, and alternative medicines.[97]

ABBREVIATIONS

ABC	ATP binding cassette
ALT	alanine aminotransferase
ANA	antinuclear antibodies
ASMA	antismooth muscle antibodies
AST	aspartate aminotransferase
BMI	body mass index (BMI = [Weight (lb)/2.205] / [(Height (in)/39.37)^2] or [Weight (kg)]/[Height (m)]^2)
CYP450	cytochrome P450 liver enzyme family
DILI	drug-induced liver injury
GGTP	gamma (γ)-glutamyltransferase
HLA	human leukocyte antigen
HSC	hepatic stellate cells
IL-9	interleukin-9, prevents apoptosis
IL-19	interleukin-19, induces apoptosis
INR	international normalized ratio
LDH	lactic dehydrogenase
LKM-1	liver kidney microsomal autoantibodies
miRNA-122	circulating micro-RNA–number 122
MDMA	methylenedioxymethamphetamine

NAFLD	nonalcoholic fatty liver disease
NAPQI	*N*-acetyl-*p*-benzoquinone imine
NASH	nonalcoholic steatohepatitis
NAT2	*N*-acetyltransferase 2 genotype
NIDDK	National Institute of Diabetes and Digestive and Kidney Diseases
SER	smooth endoplasmic reticulum
SNP	single nucleotide polymorphism
TBL	total bilirubin
TNF	tumor necrosis factor
UNL	upper normal limit for the particular laboratory test

SELF-ASSESSMENT QUESTIONS

1. Which of the following mechanisms of drug-induced liver injury are devoid of hypersensitivity features, have a long latency period, and are not associated with rapid re-injury with rechallenge?

A. Stimulation of autoimmunity

B. Disruption of calcium homeostasis

C. Non-allergic idiosyncratic reaction

D. Mitochondrial injury

2. Which drug is associated with liver vascular disorder?

A. Amiodarone

B. Ketoconazole

C. Isoniazid

D. Azathioprine

3. Which condition has a pattern of damage that originates in the hepatocytes located nearest the central vein of the liver and occurs as a result of the production of a toxic metabolite?

A. Centrilobular necrosis

B. Nonalcoholic steatohepatitis

C. Toxic cirrhosis

D. Phospholipidosis

4. Which environmental toxin has been shown to produce acute and chronic hepatic reactions?

A. Copper

B. Arsenic

C. Toluene

D. Fluorine

5. Which serum marker is a sensitive indicator for most hepatic lesions and has significant prognostic value?

A. Alanine aminotransferase

B. Aspartate aminotransferase

C. Alkaline phosphatase

D. Bilirubin

6. Which of the following signs or symptoms are commonly associated with a dysfunctioning liver?

A. Hyperglycemia

B. Hypertension

C. Abdominal Pain

D. Arthralgia

7. To assess for drug, herbal or alternative causes; what do we need to ask the patient or their available family or friends?

A. Does the patient smoke?

B. Has the patient ever been diagnosed with or suspected of alcohol misuse?

C. Does the patient exercise at least 20 minutes, at least 5 days a week?

D. Does the patient have type 1 diabetes mellitus?

8. What set of laboratory values are going to be the most useful in determining hepatocellular damage (direct damage to the hepatocytes)?

A. AST, ALT

B. γ-GTP (GGTP), Alk Phos

C. Bilirubin

D. INR, Ammonia, Transferrin

9. What set of laboratory values are going to be the most useful in determining cholestatic liver damage (direct damage to the bile canicular system)?

A. AST, ALT

B. γ-GTP (GGTP), Alk Phos

C. Bilirubin

D. INR, Ammonia, Transferrin

10. What set of laboratory values are going to be the most useful in determining a decrease in liver function during or after the injury?

A. AST, ALT

B. γ-GTP (GGTP), Alk Phos

C. Bilirubin

D. INR, Ammonia, Transferrin

11. How do individual genetic differences in cytochrome P450 phenotypes effect the susceptibility of a person to drug-induced liver injury? Patient's with (____fill in the blank____)

A. any variant slow or fast will react about the same, since cytochrome P450 is rarely involved with drug metabolism.

B. those with slow variants will be at greater risk from bioactivated free radicals.

C. those with fast variants will be at a greater risk from directly toxic drugs that do not require enzyme cleavage to harm hepatocytes.

D. slow-reacting variants will react differently then patients with very fast-reacting variants.

12. Inhibiting bile acid transport proteins can put a patient at risk for what type of liver injury, sometimes seen during pregnancy?

A. Hepatocellular Hepatitis

B. Cholestatic Hepatitis

C. Venoocclusive Disease

D. Nonalcoholic Steatosis

13. Hepatic neoplastic disorders are most strongly associated with which of the following agents?

A. Levothyroxine

B. Amoxicillin

C. Polyvinyl Chloride

D. Ritonavir

14. Hy's Law defines hepatocellular injury as a rise in ALT that is how many times above the upper limit of normal?

A. 2

B. 3

C. 4

D. 5

15. Autoimmune hepatocellular injury is often accompanied by which of the following?

A. Gouty Pain

B. ANA

C. Micro-RNA

D. Dysgeusia

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Please refer to the section on Mechanisms of Drug-Induced Liver Injury and idiosyncratic reactions. These reactions are unpredictable with our current ability to assess for vulnerable phenotypes. Antibiotics dominate as causative agents.

2. **D.** Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) and are associated with venoocclusive disease. Please refer to the section on the Patterns of Histologic Changes for additional information.

3. **A.** The damage in centrilobular necrosis spreads outward from the middle of a lobe of the liver. Please refer to the section on Patterns of Histologic Changes for additional information.

4. **B.** Please refer to the section on Assessment: Determining the Medication-Related Problem for additional information. Arsenic is found in low levels in rice, it is used in limited industrial applications and in the past as an insecticide.

5. **D.** High peak bilirubin concentrations are associated with poor survival. Please refer to the section on Assessment: Severity of the Medication-Related Problem.

6. **C.** Nausea, vomiting, diarrhea (often steaorrhea), abdominal pain, pruritis, jaundice, severe fatigue are common. Hypertension would be rare; Hyperglycemia is not helpful given its many other causes. Arthralgia would only be a common symptom during an autoimmune hepatitis.

7. **B.** Smoking is not healthy nor protective against liver injury, but it is not a strong risk factor. Alcohol misuse and moderate to heavy drinking is a distinct and powerful risk factor. Exercise is very good for preventing many things but drug-induced liver injury is not one of them. Type 2 diabetes mellitus is often associated with nonalcoholic fatty liver disorder which is a risk factor for more severe liver injury, type 1 diabetes mellitus is not associated with increased risk.

8. **A.** AST, ALT are liver enzymes released as the hepatocytes are damaged.

9. **B.** γ-GTP (GGTP), Alk Phos are liver enzymes primarily associated with the bile canicular system.

10. **D.** INR, ammonia, transferrin along with albumin and to some extent bilirubin are products or substrates of the liver and indicate liver function.

11. **D.** Cytochrome P450 enzymes often create bioactivated, highly reactive compounds. Patients with faster reacting variants of these enzyme when coupled with higher doses of drug can overwhelm detoxifying conjugating peptides, such as glutathione.

12. **B.** Selected SNPs that code for various bile salt export pumps (BSEP) are associated with rare congenital liver diseases and cholestasis during pregnancy. These patients may have a higher risk for cholestatic liver injury.

13. **C.** Androgens, estrogens, and other hormonal-related agents are frequently associated with neoplastic disease. The most documented xenobiotic-

induced hepatic cancer agent is polyvinyl chloride exposure. Used in the production of many types of plastic products, a high-quality exposure polyvinyl chloride induces angiosarcoma in exposed workers in as few as 3 years.

14. **B.** Hy's law defines hepatocellular injury as an increase in ALT that is at least three times above the upper limit of normal (UNL) with concurrent rise in TBL to a point at least 2 UNL without a significant rise in the Alk Phos.

15. **B.** Autoimmune liver injuries are mediated by the immune sys tem and are associated with elevations in ANA, IgG, ASMA, LKM-1 and associated with other immune-mediated symptoms like fever, chills, arthralgia, malaise, fatigue and vague myalgia.

Chapter e60: Evaluation of Kidney Function

Linda Awdishu; Thomas C. Dowling

KEY CONCEPTS

KEY CONCEPTS

① The stage of chronic kidney disease (CKD) should be determined for all individuals based on the level of kidney function, independent of etiology, in accordance with the Kidney Disease: Improving Global Outcomes (KDIGO) classification system.

② Persistent proteinuria indicates the presence of CKD and is associated with mortality and risk of end-stage kidney disease (ESKD).

③ Assessment of urine protein excretion, including measurement of a spot urine albumin-to-creatinine ratio, is critical for determining the severity of CKD and monitoring the rate of disease progression.

④ The glomerular filtration rate (GFR) is the single best indicator of kidney function.

⑤ Measurement of the GFR is most accurate when performed following administration of iohexol, iothalamate, or radioisotopes such as technetium-99m diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA).

⑥ Equations to estimate creatinine clearance (CL_{cr}) or GFR (eGFR) are commonly used in ambulatory and inpatient settings, and incorporate patient laboratory and demographic variables such as serum creatinine concentration (S_{cr}), cystatin C, age, sex, and weight.

⑦ Assessments of kidney structure and function, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are predominantly used for determining the diagnosis of a given condition.

BEYOND THE BOOK

BEYOND THE BOOK

Using the Drugs@FDA Website <https://www.accessdata.fda.gov/scripts/cder/daf/> or tertiary databases like Micromedex identify two commonly used drugs that require drug dose adjustments in patients with impaired kidney function. Compile a summary table of the dosing information including drug name, kidney estimation method and categories, and dose adjustment recommendation. Now consider the following patient scenarios: (1) 49-year-old Caucasian man with Scr 1.7 mg/dL (150 µmol/L), height 72 in. (183 cm), weight 100 kg; (2) 67-year-old female of African ancestry with Scr 1.5 mg/dL (133 µmol/L), height 65 in. (165 cm), weight 90 kg.

Calculate kidney function for each patient utilizing the Cockcroft–Gault equation, and the CKD EPI race free equation using Scr with and without indexing to body surface area. Compare and contrast the corresponding doses for the drugs identified using each kidney function equation. This activity is intended to build upon your understanding of kidney function and to familiarize you with how the various estimating equations may impact your dosing recommendations.

INTRODUCTION

Chronic kidney disease (CKD) continues to be a worldwide health concern, with over 2 million people in the United States estimated to require hemodialysis or kidney transplantation by 2030.[1,2] In response to this widespread problem, standardized approaches are now used for the identification of individuals with CKD and their subsequent stratification into risk categories for the development of end-stage kidney disease (ESKD) (see Chapter 62, Chronic Kidney Disease).[1,2] These efforts have heightened the awareness of the need for early identification of patients with CKD and the importance of monitoring the progression of kidney disease.

Comprehensive evaluation of kidney function requires use of qualitative, quantitative, and semi-quantitative methods. Estimation of creatinine clearance (CL_{cr}) was the clinical standard for assessment of kidney function for over 50 years. Although it continues to be used to assess kidney function for renal drug dosing purposes in pharmacokinetic studies, recent FDA guidance recommended use of estimated glomerular filtration rate (GFR) in addition to or in lieu of CL_{cr} for renal dosing recommendations.[3] Estimated GFR is routinely used across clinical settings to identify patients with CKD, and in large epidemiology studies to evaluate risks of mortality and progression to stage 5 CKD or ESKD.[4,5] Other tests, such as urinalysis, radiographic procedures, and biopsy, are also valuable tools in the assessment of kidney disease, and these qualitative assessments are useful for determining the pathology and etiology of kidney disease. Urinalysis, for example, may give clues to the primary location, such as glomerular or tubular, of the kidney disease. Follow-up studies, such as imaging procedures or kidney biopsy, may then further differentiate the specific cause, thereby guiding the selection of the optimal therapeutic intervention.

① Quantitative indices of GFR or CL_{cr} are considered the most useful diagnostic tools for identifying the presence and monitoring the progression of CKD. These measures can also be used to quantify changes in function that may occur as a result of disease progression, therapeutic intervention, or an acute insult. The measurement or estimation of CL_{cr}, however, remains the most used index for individualizing medication dosage regimens in patients with acute and CKD. It is important to note that the term *kidney function* includes the combined processes of glomerular filtration, tubular secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations in any or all these functions, whether declining or improving, are associated primarily with GFR. This chapter critically evaluates the various methods that can be used for the quantitative assessment of kidney function in individuals with normal kidney function as well as in those with CKD and acute kidney injury (AKI). Where appropriate, discussion regarding the qualitative assessment of the kidney function is also presented, including the role of imaging procedures and invasive tests such as kidney biopsy.

EXCRETORY FUNCTION

The kidney is largely responsible for the maintenance of body homeostasis via its role in regulating urinary excretion of water, electrolytes, and endogenous substances such as urea, medications, and environmental toxins. It accomplishes this through the combined processes of glomerular filtration, tubular secretion, and reabsorption.

Glomerular Filtration

Glomerular filtration is a passive process by which water and small-molecular-weight (less than 5-10 kDa) ions and molecules diffuse across the glomerular–capillary membrane into the Bowman capsule and then enter the proximal tubule (Fig. e60-1). Most proteins, such as albumin, are too large (greater than 60 kDa) to be substantially filtered, and their filtration is impeded by the electronegative charge on the epithelial surface of the glomerulus.[6] Thus, compounds presented to the glomerulus in the protein-bound state are usually not significantly filtered and remain in the peritubular circulation.

Secretion

Secretion is an active process that takes place predominantly in the proximal tubule and facilitates the elimination of compounds from the renal circulation into the tubular lumen. Several highly efficient transport pathways exist for a wide range of endogenous and exogenous substances, resulting in renal clearances of these actively secreted entities that often greatly exceed GFR and in some cases approximate renal blood flow. These transporters are typically found among the solute-linked carrier (SLC) and ATB-binding cassette (ABC) superfamilies. The primary SLC transporters include the organic anion transporting polypeptides (OATPs), organic cation transporters (OCTs), organic anion transporters (OATs), and multidrug and toxin extrusion proteins (MATEs) (Fig. e60-2). The key ABC transporters include multidrug resistance protein (MDR1 or P-glycoprotein (P-GP)), MRP1 and MRP2. Both group of transporters are expressed in a variety of different epithelial membranes throughout the body and play a role in intestinal absorption, blood–brain barrier penetration, and excretion into the bile and urine. The research has identified their localized role in drug uptake and efflux in kidney tissues, where the OCT (1-3) and OAT (1-3) are involved in basolateral influx of substrates, and P-GP, MRP, and MATE are apical efflux transporters.[7–9] Their presence in liver and kidney contributes to the hepatic and renal elimination of many drugs. For example, P-GP, which is located on the apical membrane of the proximal tubule, plays an important role in the kidney's elimination of a wide range of drugs, such as cimetidine, digoxin, and procainamide. Transporters also play a role in drug-induced kidney disease. For example, cobicisat, a CYP3A inhibitor that is used to enhance the response of several human immunodeficiency virus (HIV) regimens, has been associated with elevations in serum creatinine. The mechanism is attributed to combined inhibition of creatinine uptake (OCT2, OCT3) and efflux (MATE1).[7] The coordination of multiple drug transporters working together can result in a high degree of urinary excretion. For example, pramipexole undergoes OCT2-mediated uptake along with

MATE-mediated efflux, resulting in extensive tubular secretion and renal clearance values of 500 to 800 mL/min (8.3-13.3 mL/s).[9] Overall, the net process of tubular secretion for drugs is likely a result of multiple secretory pathways acting simultaneously. For a summary table of transporters and substrates, we refer the reader to a summary by the International Transporter Consortium.[10]

Reabsorption

Reabsorption of water and solutes occurs throughout the nephron, whereas the reabsorption of most medications occurs predominantly along the distal tubule and collecting duct. Urine flow rate and physicochemical characteristics of the molecule influence these processes: highly ionized compounds are not reabsorbed unless pH changes within the urine increase the fraction unionized, so that reabsorption may be facilitated.

Intact Nephron Hypothesis

The "intact nephron hypothesis" described by Bricker,[11] over 50 years ago, proposed that "kidney function" of patients with kidney disease is the net result of a reduced number of appropriately functioning nephrons. As the number of nephrons is reduced from the initial complement of 2 million, unaffected nephrons compensate by hyperfunctioning to establish homeostasis and a new steady state. Extensive studies have demonstrated that single-nephron GFR increases in unaffected nephrons to maintain near normal whole-kidney GFR, which represents the sum of the single-nephron

GFRs of the remaining functional nephrons. Based on this, one would presume that a measure of one component of nephron function, that is, GFR, could be used as an estimate of all functions (ie, secretion and reabsorption) of the kidney.

Glomerular Filtration Capacity

Glomerular filtration capacity and the corresponding GFR are dependent on numerous factors, one of which is protein load. The concept of renal functional reserve (RFR) has been defined as the capacity of the kidney to increase GFR in response to physiological or pathologic conditions.[12] This is similar in context to a cardiac stress test. The patient may have no hypoxic symptoms, for example, angina while resting, but it may become quite evident when the patient begins to exercise. Subjects with normal kidney function administered an oral or intravenous (IV) protein load prior to measurement of GFR have been noted to increase their GFR by as much as 50%. As kidney function declines, the kidneys usually compensate by increasing the single-nephron GFR. The RFR will be reduced in those individuals whose kidneys are already functioning at higher-than-normal levels because of preexisting kidney injury or subclinical loss of kidney mass (Fig. e60-3). Thus, RFR may be a complementary, insightful index of kidney function for many individuals with as yet unidentified CKD.

FIGURE e60-3

Structure–function relationship between GFR and nephron mass. GFR expressed in mL/min is converted to units of mL/s by multiplying by 0.0167. *(Reprinted, with permission, from Sharma A, Mucino MJ, Ronco C. Renal functional reserve and renal recovery after acute kidney injury. Nephron Clin Pract. 2014;127:94-100.)*

Quantification of kidney function is not only an important component of a diagnostic evaluation, but it also serves as an important parameter for monitoring therapy directed at the etiology of the diminished function itself, thereby allowing for objective measurement of the success of treatment. Measurement of kidney function also serves as a useful indicator of the ability of the kidneys to eliminate drugs from the body. Furthermore, alterations of drug distribution and metabolism have been associated with loss of kidney function. The pharmacokinetic changes in patients with kidney disease are extensively reviewed in Chapter 67, Personalized Pharmacotherapy for Patients with Chronic Kidney Disease. Although several indices have been used for the measurement of GFR in the research setting, estimation of CL_{cr} and GFR are the primary approaches used in the clinical arena.

ENDOCRINE FUNCTION

The kidney synthesizes and secretes many hormones involved in maintaining fluid and electrolyte homeostasis. Secretion of renin by the cells of the juxtaglomerular apparatus and production and metabolism of prostaglandins and kinins are among the kidney's endocrine functions. Additionally, in response to decreased oxygen tension in the blood, which is sensed by the kidney, erythropoietin is produced and secreted by peritubular fibroblasts.

Because these functions are related to kidney mass, decreased endocrine activity is associated with the loss of viable kidney cells. In patients with stages 3 to 5 CKD and those with moderate-to-severe AKI, secretion of erythropoietin is impaired leading to reduced red blood cell formation, normocytic anemia, and symptoms of reduced oxygen delivery to tissues such as fatigue, dyspnea, and angina (see Chapter 62, Chronic Kidney Disease). Indeed, anemia-induced kidney hypoxia results indirectly in erythropoietin gene activation, tubular necrosis, and apoptosis, thereby contributing to further kidney cell injury.

METABOLIC FUNCTION

The kidneys perform a wide variety of metabolic functions, including the activation of vitamin D, gluconeogenesis, and metabolism of endogenous compounds such as insulin, steroids, and xenobiotics. It is common for patients with diabetes and stages 4 to 5 CKD to have reduced requirements for exogenous insulin, and require supplemental therapy with activated vitamin D_3 (calcitriol) or other vitamin D analogs (paricalcitol, doxercalciferol) to avert the bone loss associated with CKD-associated metabolic bone disease (see Chapter 63, Chronic Kidney Disease: Management of Secondary Complications). Cytochrome P450 (CYP), *N*-acetyltransferase, glutathione transferase, renal peptidases, and other enzymes responsible for the degradation and activation of selected endogenous and exogenous substances have been identified in the kidney. The CYP enzymes in the kidneys are as active as those in the liver, when corrected for organ mass, and their function may be impaired in the presence of kidney failure or uremia. Impaired nonrenal clearance in the presence of kidney failure has been documented for a number of drugs with a fraction eliminated renally unchanged of less than 30%, including those that undergo extensive CYP metabolism by CYP1A2, CYP2D6, CYP3A4, and CYP2C9, such as duloxetine, rosuvastatin, and telithromycin.[13]

QUALITATIVE AND SEMI-QUANTITATIVE INDICES OF KIDNEY FUNCTION

Patients who develop CKD remain relatively asymptomatic until they reach stage 4 to 5 and systemic manifestations and/or secondary complications become evident. As kidney function declines, patients may develop new onset or worsening hypertension, edema, electrolyte abnormalities, anemia, or other complications (see Chapter 62, Chronic Kidney Disease). The Kidney Disease Outcomes Quality Initiative (KDOQI) workgroup recommends that all patients with CKD, and at increased risk for CKD, undergo a comprehensive laboratory assessment that comprises (a) S_{cr} to estimate GFR; (b) albumin-to-ceatinine ratio in a spot urine specimen; (c) examination of urine sediment for red blood cell and white blood cell counts; (d) serum electrolytes, including sodium, potassium, chloride, and bicarbonate; (e) urine pH; and (f) urine specific gravity.[14] Kidney ultrasound and additional diagnostic tests such as urine electrolytes may aid in evaluating the etiology of kidney disease.

LABORATORY PROCEDURES TO DETECT THE PRESENCE OF KIDNEY DISEASE

Urinalysis is an important tool for detecting and differentiating various aspects of kidney disease, which often goes unnoticed as the result of its asymptomatic presentation. Urinalysis can be used to detect and monitor the progression of diseases such as diabetes, glomerulonephritis, and chronic urinary tract infections. A typical urinalysis provides information about physical and chemical composition, most of which can be completed quickly and inexpensively by visual observation (volume and color) and dipstick testing.

Chemical Analysis of Urine

pH

The normal urine pH typically ranges from 4.5 to 7.8, and an elevation above this may suggest the presence of urea-splitting bacteria. In patients with renal tubular acidosis, urine pH is usually more than 5.5 because of impaired hydrogen ion secretion in the distal tubule or collecting duct.

Glucose

Glucose is usually not present in the urine because the kidney normally completely reabsorbs all the glucose filtered at the glomerulus. When a patient's blood glucose concentration exceeds the maximum threshold for glucose reabsorption (~180 mg/dL [10.0 mmol/L]), glucosuria will be present. Routine assessment of glucosuria to monitor diabetes has been replaced by newer methods of direct blood glucose measurements. Urine glucose testing is now predominantly used as a screening tool for the detection of diabetes. Glucosuria may be used as a monitoring parameter for the efficacy of sodium glucose co-transporter 2 (SGLT2) inhibitors.

Ketones

Acetoacetate and acetone are not normally found in the urine; they are however excreted in patients with diabetic ketoacidosis. They are also present under conditions of fasting or starvation. Typically, values of acetoacetate excretion are reported as small (less than 20 mg/dL [2 mmol/L]), moderate (30-40 mg/dL [3-4 mmol/L]), and large (greater than 80 mg/dL [8 mmol/L]).

Nitrite

Nitrite is not usually present in urine. The presence of nitrite is most commonly the result of conversion from urinary nitrate by bacteria in the urine. The presence of nitrite suggests that the patient has a urinary tract infection, commonly caused by gram-negative rods such as *Escherichia coli*. Although false-positive results are very rare, false-negative results are more common and may be caused by lack of dietary nitrate, reduced urine nitrate concentration from diuresis, or infections caused by bacteria such as enterococci and *Acinetobacter*, which do not reduce nitrate, and pseudomonads, which convert nitrate to nitrogen gas.

Leukocyte Esterase

Leukocyte esterase is released from lysed granulocytes in the urine; its presence is suggestive of urinary tract infection. False-positive tests can result from delayed processing of the urine sample, contamination of the sample with vaginal secretions (such as blood or heavy mucus discharge), or by *Trichomonas* infection (such as trichomoniasis). False-negative tests can be produced by the presence of high levels of protein or ascorbic acid.

Heme

The heme test indicates the presence of hemoglobin or myoglobin in the urine. A positive test without the presence of red blood cells suggests either red cell hemolysis or rhabdomyolysis. In patients with established CKD, the presence of hematuria (positive dipstick) may be a significant risk factor for worsening CKD and death.[15]

Protein or Albumin

② Evaluation of urinary protein or albumin is a standard tool to characterize the severity of CKD and to monitor the rate of disease progression or regression.[14] Persistent proteinuria or albuminuria, which is present on at least three occasions over a period of 3 to 6 months, is now considered a principal marker of kidney damage. Under normal conditions, plasma proteins remain in the glomerular capillaries and thus do not cross the glomerular basement membrane or enter the urinary space. Some of these proteins, such as albumin and globulins, are not filtered by the glomerulus as a result of charge and size selectivity (albumin 69 kDa). Smaller proteins (less than 20 kDa) pass across the glomerular basement membrane but are usually readily reabsorbed in the proximal tubule. Most healthy individuals excrete between 30 and 150 mg/day of total protein consisting of approximately 30 mg/day of albumin. The other proteins that may be found in the urine are secreted by the tubules (Tamm-Horsfall, immunoglobulin A, and urokinase) or composed of smaller proteins such as β_2-microglobulin, apoproteins, enzymes, or peptide hormones. Increased renal excretion of these low-molecular-weight proteins is considered a sensitive marker of tubulointerstitial disease.

Dipstick tests are the most common means to determine in a semi-quantitative fashion a patient's urinary protein or albumin excretion. False-positive results can occur in the presence of alkaline urine (pH greater than 7.5), when the dipstick is immersed too long, in those with highly concentrated urine, in the presence of drugs such as penicillin, sulfonamides, or tolbutamide, as well as blood, pus, semen, or vaginal secretions. False-negative results occur with dilute urine (specific gravity less than 1.015) and when proteinuria is caused by non-albumin or low-molecular-weight proteins such as heavy or light chains or Bence Jones proteins. The results of these dipstick tests are graded as negative (less than 10 mg/dL [100 mg/L]), trace (10-20 mg/dL [100-200 mg/L]), 1+ (30 mg/dL [300 mg/L]), 2+ (100 mg/dL [1,000 mg/L]), 3+ (300 mg/dL [3,000 mg/L]), or 4+ (greater than 1,000 mg/dL [10,000 mg/L]). Benchtop portable analyzers designed for point-of-care testing are increasingly used as an alternative to visual urinalysis test-strip evaluation and provide rapid results for urinary albumin-to-creatinine ratio.

③ Dipstick test strips that are specific for low levels of albuminuria (30-300 mg/day) should be employed when one is screening individuals at risk for CKD. For example, the Accutest Microalbumin/Creatinine 2-1 Strips (Jant Pharmacal) is a semi-quantitative test for both albumin and creatinine in a spot urine sample. In patients with a positive protein or albumin dipstick test, a 24-hour urine collection with measurement of albumin excretion can be used to precisely quantitate the degree of albuminuria. However, this method requires a high degree of patient compliance and is being replaced by a similarly accurate but less cumbersome technique: calculation of the ratio of protein or albumin (in milligrams) to creatinine (in grams [or mmol]) in an untimed (spot) urine specimen. The normal ratio, KDIGO category A1, is less than 30 mg albumin or less than 150 mg protein per gram of creatinine (3 mg albumin per mmol of creatinine or 15 mg protein per mmol of creatinine).[2] Category A2 is values between 30 and 300 mg/g (3.4 to 33.9 mg/mmol)and A3 is greater than 300 mg/g (33.9 mg/mmol).[2] Positive test results should be repeated, particularly in patients without an underlying cause for CKD, such as diabetes or hypertension. Monitoring CKD progression involves routine measurement of the albumin-to-creatinine ratio (UACR), whereas for patients with advanced CKD or KDIGO category A3, the protein-to-creatinine ratio (PCR) can be used to monitor kidney disease progression.

The albumin-to-creatinine ratio has also been incorporated into a CKD classification system as recommended by a Work Group of the Kidney Disease: Improving Global Outcomes (KDIGO).[2] This standardized “CGA” scoring system requires evaluation of both estimated GFR (G1-G5) and albuminuria (A1-A3) in a given patient. This approach aids in evaluating prognosis of CKD outcomes rather than relying on estimated glomerular filtration rate (eGFR) alone. A detailed description of how to apply this CGA classification system in the monitoring plan for CKD patients is provided in Chapter 62, Chronic Kidney Disease.

Specific Gravity

Specific gravity is a measure of urine weight relative to water (1.00) that is performed using a refractometer. Thus, specific gravity is dependent on water intake and urine-concentrating ability. Normal values range from 1.003 to 1.030. Osmolality, which is a measure of the number of solute particles in the urine, is a more accurate measure of the kidney’s ability to make a concentrated urine. Generally, the two values correlate; however, when large quantities of heavier molecules, such as glucose, are in the urine, the specific gravity may be elevated relative to the osmolality. These tests are used in the assessment of urine-concentrating ability and are most informative when interpreted along with the hydration status of the patient and plasma osmolality.

Microscopic Analysis of Urine

Microscopic examination of the urine is helpful to evaluate the etiology of kidney injury or disease. Formed elements that may be detected in the urine include erythrocytes and leukocytes, casts, and crystals which aids in the differential diagnosis. Hematuria may be glomerular, renal, or urologic in etiology. Hematuria is defined as more than three red blood cells per high-power field (HPF), and the presence of dysmorphic red blood cells suggest glomerular etiology. White blood cells may be present in the urine in association with infection or inflammatory conditions, such as interstitial nephritis. More than two cells/HPF for men and 5 cells/HPF for women is usually considered abnormal. Contamination of the sample should also be considered when there are many cells and may be a result of the presence of menses or of inadequate sample collection. Casts are cylindrical and composed of Tamm-Horsfall mucoprotein and contents of tubule lumen. They originate from the distal convoluted tubule or collecting duct during periods of urinary concentration or very low urinary pH. The predominant contents determine the type of cast: hyaline, erythrocyte, leukocyte, epithelial, granular, waxy, fatty, or broad.

A variety of crystals may be visualized in the urinary sediment in healthy individuals as well as those with kidney diseases. The most common crystals are those composed of uric acid, calcium oxalate, calcium phosphate, calcium magnesium ammonium pyrophosphate, and cystine. Many of these have a unique crystalline form, which permits them to be identified with microscopy. Images of common types of urinary casts and crystals can be found at publicly available Web sites such as https://openi.nlm.nih.gov/detailedresult?img=PMC4525130_cnr-4-137-g001&req=4 [Last Accessed August 4, 2022].

Serum or Blood Urea Nitrogen

Amino acids metabolized to ammonia are subsequently converted in the liver to urea, the production of which is dependent on protein availability (diet) and hepatic function. Urea undergoes glomerular filtration followed by reabsorption of up to 50% of the filtered load in the proximal tubule. The normal blood urea nitrogen (BUN) is in the range of 5 to 20 mg/dL (1.8-7.1 mmol/L). The reabsorption rate of urea is predominantly dependent on the reabsorption of water. The excretion of urea may, therefore, be decreased under conditions that necessitate water conservation such as dehydration, although the GFR may be normal or only slightly reduced. This condition is evident when a patient exhibits prerenal azotemia, or an increase of the BUN to a greater extent than the S_{cr}. The normal BUN-to-creatinine ratio is 10 to 15:1 using conventional units (or 40-60:1 when both are expressed in identical molar units), and an elevated ratio is suggestive of a decreased effective circulating volume, which stimulates increased water, and hence, urea reabsorption. Creatinine is not reabsorbed to any significant extent by the kidneys. Despite these limitations, the BUN is usually used in combination with the S_{cr} as a simple screening test for the detection of kidney dysfunction.

Serum and Urine Creatinine

Creatinine remains the most widely used endogenous biomarker for the detection of kidney disease. The concentration of creatinine in serum is a function of creatinine production and kidney excretion. Creatinine is a product of creatine metabolism from muscle; therefore, its production is directly dependent on muscle mass. At steady state, the “normal” S_{cr} range is generally reported as 0.5 to 1.2 mg/dL (44-106 µmol/L) for males and females. Creatinine is eliminated primarily by glomerular filtration, and as GFR declines, the S_{cr} rises (Fig. e60-4).

FIGURE e60-4

Relationship between serum creatinine and creatinine clearance.

The National Health and Nutrition Examination Survey (NHANES) revealed a mean S_{cr} in Caucasian women and men of 0.73 mg/dL (65 µmol/L)and 0.95 mg/dL (84 µmol/L), respectively.[16] Values were lower among people of Mexican descent, and higher among those of African descent. For all groups, the S_{cr} increased with age. Although the S_{cr} alone is not an optimal measure of kidney function, it is often used as a marker for referral to a nephrologist. There is presently no accepted single standard for an “abnormal” S_{cr}, as it is dependent on gender, age, and lean body mass.

Standardized S_{cr} assays are now used in most hospital clinical laboratories.[17] The method involves calibration of creatinine values based on standardized reagents that are traceable to an isotope dilution-mass spectrometry (IDMS) method. This approach has significantly reduced interlaboratory variability in S_{cr} values, and has resulted in a downward shift of the “normal range” for S_{cr} values by 0.1 to 0.2 mg/dL (9-18 µmol/L) compared to noncalibrated ranges. Other modifications include reporting S_{cr} values in mg/dL to two decimal places (eg, 0.93 mg/dL), and values in µmol/L to the nearest whole number (eg, 82 µmol/L). This practice is aimed at reducing rounding errors which previously contributed to bias between creatinine-based GFR or CL_{cr} estimates, but it does not improve GFR estimation in those without CKD.

Despite alterations in creatinine assay methods, many drugs such as 5-flucytosine or dobutamine may interfere with these assays resulting in false elevations or reductions in S_{cr} values. Other compounds are known to increase S_{cr} by inhibition of active tubular secretion. Among these are cimetidine and trimethoprim, which compete for creatinine secretion at the cationic transport system in a dose-dependent fashion. Other drugs known to interfere with the active tubular secretion of creatinine include rilpivirine, dolutegravir, cobicistat, pyrimethamine, and amiodarone. These interactions typically result in S_{cr} elevations of 0.1 to 0.4 mg/dL (0.9-35 μmol/L) with apparent reductions in CL_{cr} of up to 30 mL/min/1.73 m^2 (0.29 mL/s/m^2).[18]

The S_{cr} is dependent on the “input” function, or formation rate, and “output” function, or elimination rate. Its formation rate depends on the zero-order production from creatine metabolism, as well as input from other sources, such as dietary intake. Over 95% of creatine stores are found in skeletal muscle, with creatine metabolism being directly proportional to muscle mass. Thus, individuals with more muscle mass have a higher S_{cr} at any given degree of kidney function than those with less muscle mass. Strenuous exercise is associated with an increase of approximately 10% in the S_{cr}. In contrast, cachectic patients, as the result of minimal muscle mass, will have very low S_{cr}, as do those with spinal cord injuries. Elderly patients and those with poor nutrition may also have low S_{cr} (less than 1.0 mg/dL [88 μmol/L]) secondary to decreased muscle mass.

Creatine or methyl guanidine acetic acid is found in many commonly ingested food sources such as fish and red meat. During the cooking of meat, some creatine is converted to creatinine, which is rapidly absorbed following ingestion. S_{cr} may rise as much as 50% within 2 hours of a meat meal and remain elevated for as long as 8 to 24 hours.[19] Creatine is used as a dietary supplement to increase skeletal muscle stores of phosphocreatine, leading to adenosine triphosphate (ATP) resynthesis of adenosine diphosphate (ADP). The effect of creatine ingestion on the S_{cr} concentration is unclear. Short- and long-term administration of creatine increases S_{cr} by 25% to 40%[20] Thus, it is important to question ambulatory patients regarding their dietary intake for the 24 hours preceding the measurement of S_{cr} or CL_{cr}.

Diurnal variation in S_{cr} may also affect the accuracy of the CL_{cr} determination. Although the fluctuation is minimal, the observed peak plasma creatinine concentration generally occurs at approximately 7:00 PM, whereas the nadir is in the morning. The impact of diurnal variation is minimized by using S_{cr} measurements that are drawn at similar times during longitudinal evaluations, or using 24-hour urine collections for CL_{cr} measurements.

Serum and Urine Cystatin C

Cystatin C (cysC) is a 132-amino-acid (13.3-kDa) cysteine protease inhibitor produced by all nucleated cells of the body that is considered a biomarker of kidney function. It is freely filtered at the glomerulus and undergoes both reabsorption and catabolism in the proximal tubule. The renal handling of this biomarker is distinctly different from creatinine and exogenous GFR markers such as inulin, iohexol, and iothalamate. Originally introduced in Europe, it was recommended as a biomarker of kidney function because of findings that serum concentrations significantly correlated with GFR and S_{cr}. The range of normal serum cysC values is 0.55 to 1.18 mg/L (41-88 nmol/L) for women and 0.60 to 1.11 mg/L (45-83 nmol/L) for men based on data from the NHANES study.[21] It was hypothesized that since cysC production is not affected by muscle mass, it would provide a more reliable estimate of kidney function than S_{cr}. It is known that serum cysC concentrations can be altered by many factors other than kidney function, such as age, nutritional status, gender, weight, height, cigarette smoking, serum C-reactive protein levels, steroid therapy, and rheumatoid arthritis.[22] Serum cysC concentration has been shown to perform better than S_{cr} for predicting contrast-induced kidney injury, resulting in a new definition of contrast-induced acute kidney injury (CI-AKI), consisting of a more than 10% increase in cysC within 24 hours after exposure to contrast media.[23] Serum cysC also detected AKI up to 2 days earlier than S_{cr} in critically ill patients,[24] and cysC concentration was a better predictor of AKI in pediatric cardiac surgery patients.[25] However, serum cysC may be a less sensitive biomarker than creatinine for detecting AKI in the postoperative period.[26] Post-op cardiac surgery patients with elevated urinary cysC-to-creatinine ratios had the highest prevalence of developing AKI.[27] S_{cr} does not peak until 48 hours after intensive care unit (ICU) admission, suggesting that urinary cysC may be beneficial in early diagnosis of AKI. Because it is normally reabsorbed and metabolized in the renal proximal tubule, it is hypothesized that tubular damage would lead to increased urinary excretion of cysC. These differential findings suggest that the role of cysC in assisting with the diagnosis of AKI is yet to be fully determined.

Urinary Biomarkers for Detection of Acute Kidney Injury

Urinary biomarkers, such as kidney injury molecule-1 (KIM-1), neutrophil gelatinase-associated lipocalin (NGAL), among others, have shown promise in detecting AKI (see Chapter 61, Acute Kidney Injury). β-Trace protein (BTP) has also been proposed as an alternate endogenous marker of GFR.

Similar to cysC, it is a low-molecular-weight glycoprotein (168 amino acids) that is filtered through the glomerular basement membrane and reabsorbed in the renal proximal tubule. Elevated serum concentrations of BTP may be seen in patients with CKD,[28] kidney transplant recipients,[29] and children.[30] Other markers of early AKI include urinary tissue inhibitor of metalloproteinase 2 (TIMP-2) and urinary insulin-like growth factor binding protein 7 (IGFBP-7). These two biomarkers are important because they are involved in G1 cell cycle arrest of renal tubular cells during the early period of cell injury. Combining these markers into a duplex “TIMP-2 × IGFBP-7” biomarker algorithm in over 500 patients accurately predicted AKI following cardiac surgery in high-risk patients.[31,32] These results supported the FDA approval of NephroCheck® (Astute Medical, Inc; https://www.nephrocheck.com/us/) as a urinary diagnostic device indicated for early detection of AKI.

MEASUREMENT OF KIDNEY FUNCTION

The gold standard quantitative index of kidney function is a measured GFR (mGFR). A variety of methods may be used to measure and estimate kidney function in the acute care and ambulatory settings. Measurement of GFR is important for early recognition and monitoring of patients with CKD.

It is important to recognize conditions that may alter kidney function independent of underlying renal pathology. For example, protein intake, such as oral protein loading or an infusion of amino acid solution, may increase GFR. As a result, inter- and intrasubject variability must be considered when GFR is used as a longitudinal marker of kidney function. Dietary protein intake correlates with GFR in healthy subjects. Subjects who are vegetarian have a lower GFR because of their reduced dietary protein intake relative to individuals who consume a similar caloric but normal-protein-content diet. Findings from the nurses’ health study[33] indicate that longitudinal changes in GFR are independent of the source of protein (nondairy animal, dairy, or vegetable) in women with normal kidney function. However, women with mild renal insufficiency (GFR 71 ± 7 mL/min [1.18 ± 0.12 mL/s]) who consumed the highest amount of protein (93 g/day) had a threefold greater risk of a more than or equal to 5 mL/min (0.08 mL/s) decline in GFR compared to the lowest protein group (60 g/day); rates of decline were highest in those consuming nondairy animal protein. The increased GFR following a protein load is the result of renal vasodilation accompanied by an increased renal plasma flow. Therefore, assessment of a mGFR must consider the dietary protein status of the patient at the time of the study.

Measurement of Glomerular Filtration Rate

④ A mGFR remains the single best index of kidney function, and this method is routinely employed worldwide in the evaluation of kidney transplant recipients and donors. As renal mass declines in the presence of age-related loss of nephrons or disease states such as hypertension or diabetes, there is a progressive decline in GFR. The rate of decline in GFR can be used to predict the time to onset of stage 5 CKD, and the risk of complications of CKD.

The GFR is expressed as the volume of plasma filtered across the glomerulus per unit time, based on total kidney blood flow and capillary hemodynamics. The normal values for GFR are 127 ± 20 mL/min/1.73 m^2 (1.22 ± 0.19 mL/s/m^2) and 118 ± 20 mL/min/1.73 m^2 (1.14 ± 0.19 mL/s/m^2) in healthy men and women, respectively. These measured values closely approximate what one would predict if the normal kidney blood flow was approximately 1000 mL/min/1.73 m^2 (9.63 mL/s/m^2), plasma volume was 60% of blood volume, and filtration fraction across the glomerulus was 20%. In that situation the normal GFR would be expected to be approximately 120 mL/min/1.73 m^2 (1.16 mL/s/m^2).

Optimal clinical measurement of GFR involves determining the renal clearance of a substance that is freely filtered without additional clearance because of tubular secretion or reduction as the result of reabsorption. Additionally, the substance should not be susceptible to metabolism within renal tissues and should not alter kidney function. Given these conditions, the mGFR is equivalent to the renal clearance of the solute marker:

$$\mathrm{GFR} = \mathrm{renalCL} = (A_e)/\mathrm{AUC}_{0-t}$$

where renal CL is renal clearance of the marker, A_e is the amount of marker excreted in the urine in a specified period of time, t, and AUC_{0-t} is the area under the plasma-concentration-versus-time curve of the marker.

Under steady-state conditions, for example, during a continuous infusion of the marker, the expression simplifies to

$$\mathrm{GFR} = \mathrm{renalCL} = (A_e)/[(C_{ss}) \times t]$$

where C_{ss} is the steady-state plasma concentration of the marker achieved during continuous infusion. The continuous infusion method can also be employed without urine collection, where plasma clearance is calculated as CL = infusion rate/C_{ss}. This method is dependent on the attainment of steady-state plasma concentrations and accurate measurement of infusate concentrations. Plasma clearance can also be determined following a single-dose IV injection with the collection of multiple blood samples to estimate area under the curve ($AUC_{0-\infty}$). Here, clearance is calculated as CL = dose/AUC. These plasma clearance methods commonly yield clearance values 10% to 15% higher than GFR measured by urine collection methods.[34]

5 Several markers have been used for the measurement of GFR and include both exogenous and endogenous compounds (see Table e60-1). Although they generally provide an accurate measurement, use of exogenous GFR markers such as inulin, sinistrin, iothalamate, iohexol, and radioisotopes requires specialized administration techniques and detection methods for the quantification of concentrations in serum and urine so are not practical for routine clinical use. They are most commonly used in the research setting. Conversely, methods that employ endogenous compounds, such as creatinine or cysC, require less technical expertise, but produce results with greater variability. The GFR marker of choice depends on the purpose and cost of the compound. Radiolabeled compounds such as ^{125}I-iothalamate are more expensive than nonradiolabeled iothalamate (Conray-60, Mallincrodt) or iohexol.

TABLE e60-1

Markers of Kidney Function

Renal plasma/blood flow	PAH ^{131}I-OIH ^{99m}Tc-MAG3
Glomerular filtration rate	Inulin, sinistrin Iothalamate Iohexol ^{99m}Tc-DTPA ^{125}I- Iothalamate Creatinine cysC
Tubular function	PAH NMN TEA β_2-Microglobulin RBP Protein HC (α_1-microglobulin) NAG AAP ABP

^{1}I-OIH, ^{131}I-orthoiodohippurate; ^{99m}Tc-DTPA, ^{99m}Tc-diethylenetriaminepentaacetic acid; ^{99m}Tc-MAG3, ^{99m}Tc-mercaptoacetyltriglycine; AAP, alanine aminopeptidase; ABP, adenosine binding protein; cysC, cystatin C; NAG, *N*-acetylglucosaminidase; NMN, N^1-methylnicotinamide; PAH, *p*-aminohippurate; RBP, retinol-binding protein; TEA, tetraethylammonium.

Iothalamate Clearance

Iothalamate is an iodine-containing radiocontrast agent that is available in both radiolabeled (^{125}I) and non-radiolabeled forms. This agent is handled in a manner similar to that of inulin; it is freely filtered at the glomerulus and does not undergo substantial tubular secretion or reabsorption. The nonradiolabeled form is most widely used to measure GFR in ambulatory and research settings, and can safely be administered by IV bolus, continuous infusion, or subcutaneous injection. Plasma clearance methods that do not require urine collections are highly correlated with renal clearance, making them particularly well-suited for longitudinal evaluations of kidney function.[35] These plasma clearance methods require two-compartment modeling approaches because accuracy is dependent on duration of sampling. For example, short sampling intervals can overestimate GFR, particularly in patients with severely reduced GFR.[35] In individuals with GFR more than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), a 2-hour sampling strategy yields GFR values that are up to 54% higher compared with 10-hour sampling, whereas the 5-hour sampling is 17% higher. In individuals with GFR less than 30 mL/min/1.73 m^2 (0.29 mL/s/m^2), 5-hour GFR is 36% higher and 2-hour GFR is 126% higher than the 10-hour measurement. Hence, a 5- to 7-hour sampling period with eight plasma samples may be the most appropriate and feasible approach for most GFR evaluations.

Iohexol

Iohexol, a nonionic, low osmolar, iodinated contrast agent, is widely used as a gold standard measure of GFR. Iohexol has a molecular weight of 821 Da, is low protein binding, and is eliminated almost entirely by glomerular filtration. Iohexol plasma and renal clearance strongly correlate with iothalamate and support use of iohexol as an alternative marker for the measurement of GFR. One advantage of this agent is that a limited number of plasma samples can be used to quantify iohexol plasma clearance, with as few as a single sample.[36] The sampling time depends on the subject's eGFR: 180 min if GFR is normal, 300 to 360 min if GFR between 30 and 60 mL/min (0.5 to 1 mL/s) and 600 to 1440 min if GFR is below 30 mL/min (0.5 mL/s).[37–39]

$\text{Equation}: \text{GFR} = (1/(t/V + 0.0016) * \ln(\text{Dose}/(V * Ct)(\text{inmL min}))$ Equation:GFR=(1/(t/V+0.0016)*ln (Dose/(V*Ct)(inmLmin))
Vmale: 166 *W+ 2490

Vfemale: 95*W+ 6170

Ct is the sample concentration (μg/mL) at time t (minute), V is the apparent volume of distribution (mL), and W is the weight (kg).

In Sweden, a mGFR using plasma iohexol clearance is routinely employed to monitor advanced CKD progression during the pretransplant period.[40]

Radiolabeled Markers

The GFR has also been quantified using radiolabeled markers, such as ^{125}I-iothalamate (614 Da, radioactive half-life of 60 days), ^{99m}Tc-DPTA (393 Da, radioactive half-life of 6.03 hours), and ^{51}Cr-ethylenediaminetetraacetic acid (^{51}Cr-EDTA; 292 Da, radioactive half-life of 27 days).[41] These relatively small molecules are minimally bound to plasma proteins and do not undergo tubular secretion or reabsorption to any significant degree. ^{125}I-iothalamate and ^{99m}Tc-DPTA are used in the United States, whereas ^{51}Cr-EDTA is used extensively in Europe. The use of radiolabeled markers allows one to determine the individual contribution of each kidney to total kidney function. The nonrenal clearance of these agents is low (3-8 mL/min [0.05-0.13 mL/s]), suggesting that plasma clearance is an acceptable technique except in patients with severe renal insufficiency (GFR less than 30 mL/min [0.50 mL/s]). Indeed, highly significant correlations between renal clearance among radiolabeled markers has been demonstrated.[41] Although total radioactive exposure to patients is usually minimal, use of one of these agents does require compliance with radiation safety committees and appropriate biohazard waste disposal.

Optical Real-Time Glomerular Filtration Rate Markers

A clinically applicable technique to rapidly measure GFR, particularly in critically ill patients with unstable kidney function, is highly desirable. The currently available GFR measurement approaches, as outlined above, are technically demanding, time-consuming, and often cost-prohibitive, so they are not practical for routine clinical use. Rapid, accurate, safe, and inexpensive techniques are in development to address this need. For example, small, nontoxic, exogenously administered fluorescent tracers are being investigated for "real-time" GFR measurement, and at least two have entered early-phase clinical trials. Both methods involve administration of optically active compounds, with continuous detection of the fluorescence signal using fiber optic or photonics technologies. One system involving injection of fluorescent dextran molecules with blood sampling and rapid (bedside) detection over 120 minutes (FAST BioMedical; Indianapolis, IN).[42] Another method involves injection of a hydrophilic pegylated pyrazine dye (MB-102), with continuous detection using a transdermal noninvasive optical renal function monitor (ORFM) device (MediBeacon, LLC; St. Louis, MO).[43]

Measured Creatinine Clearance

Although the measured CL_{cr} (mCL_{cr}) has been used as an approximation of GFR for decades, it has limited clinical utility for a multiplicity of reasons. Short-duration witnessed mCL_{cr} correlates well with mGFR based on iothalamate clearance performed using the single-injection technique. However, diurnal variations in S_{cr} may impact CL_{cr}. This test is usually performed over a 24-hour period with the S_{cr} obtained in the morning. Inaccuracy can result from over- or under- collections, and interconversion between creatinine and creatine when urine is not maintained at a pH less than 6.

An important limitation of using creatinine as a filtration marker is that it undergoes tubular secretion. Tubular secretion augments the filtered creatinine by approximately 10% in subjects with normal kidney function. Tubular secretion, however, increases to as much as 100% in patients with kidney disease, resulting in mCL_{cr} values that markedly overestimate GFR. In CKD stage 4-5, one approach is to measure creatinine and urea in a 24-hour collection and take an average of the clearance of these small molecules. Since urea is freely filtered and reabsorbed, averaging its clearance with creatinine adjusts the over-estimation based on creatinine alone.

Estimation of Glomerular Filtration Rate

⑥ Serum creatinine and other clinical variables are used to calculate eGFR. These estimates are commonly used for the detection, diagnosis, and management of kidney diseases. Creatinine-based eGFR guide our clinical decision making, especially as it pertains to the initiation, discontinuation, and dosing of medications. Clinical laboratories in the United States automatically calculate and report eGFR when reporting basic or comprehensive metabolic panels that contains serum creatinine. Many GFR estimating equations have been developed (see Table e60-2). The initial equation was derived from multiple regression analysis of data obtained from the 1,628 patients enrolled in the Modification of Diet in Renal Disease (MDRD) study where GFR was measured using the clearance of ^{125}I-iothalamate as a gold standard.[44] The original four-variable MDRD equation based on Scr, age, sex, and race was updated with the standardization of the Scr assay (MDRD4-IDMS). However, this equation was shown to be inaccurate at GFR greater than 60 mL/min/1.73 m^2, for reasons not associated with standardization of S_{cr} (IDMS) assay results. The MDRD equation is no longer recommended for clinical use and has since been replaced with newer eGFR equations described below.

TABLE e60-2

Equations for the Estimation of Glomerular Filtration Rate in Adults with Stable Kidney Function

Creatinine-based eGFR equations	
MDRD-IDMS[93]	eGFR = 175 × $(S_{cr})^{-1.154}$ × $(\text{age})^{-0.203}$ × (0.742 if patient is female) × (1.210 if Black patient)
CKD-EPI $_{\text{creat}}$[45]	eGFR = 141 × $\min(S_{cr}/\kappa, 1)^{\alpha}$ × $\max(S_{cr/,}\kappa, 1)^{-1.209}$ × 0.993^{Age} × 1.018 [if female] × 1.159 [if Black patient]
CKD-EPI$_{\text{creat}}$ (race free)[58]	eGFR = 142 × $\min(SCr/\kappa, 1)^{\alpha}$ × $\max(S_{cr}/\kappa, 1)^{-1.2}$ × 0.9938^{Age} × 1.012 [if female]
Cystatin C–based eGFR equations	
CKD-EPI$_{\text{cysC}}$[49]	eGFR = 133 × $\min(\text{cysC}/0.8, 1)^{-0.499}$ × max $(\text{cysC}/0.8, 1)^{-1.328}$ × 0.996(age) × 0.932 [if female]
CKD-EPI$_{\text{creat-cysC}}$[49]	eGFR = 135 × $\min(S_{cr}/\kappa, 1)^{\alpha}$ × $\max(S_{cr}/\kappa, 1)^{-0.601}$ × $\min(\text{cysC}/0.8, 1)^{-0.375}$ × $\max(\text{cysC}/0.8, 1)^{-0.711}$ × 0.995^{Age} × 0.969 [if female] × 1.08 [if Black patient]
CKD-EPI$_{\text{creat-cysC}}$ (race free)[58]	eGFR = 135 × $\min(S_{cr}/\kappa, 1)^{\alpha}$ × $\max(S_{cr}/\kappa, 1)^{-0.544}$ × $\min(\text{cysC}/0.8, 1)^{-0.323}$ × $\max(\text{cysC}/0.8, 1)^{-0.778}$ × 0.996^{Age} × 0.963 [if female]

CKD, chronic kidney disease; cysC, cystatin C; eGFR, estimated glomerular filtration rate; min, minute; S_{cr}, serum or plasma creatinine (mg/dL).

κ is 0.7 for females and 0.9 for males, min indicates the minimum of S_{cr}/κ or 1, and max indicates the maximum of Scr/κ or 1. For SI conversion purposes serum/plasma creatinine is converted from µmol/L to mg/dL by multiplying by 0.0113. Conversion from eGFR conventional units of mL/min/1.73 m^2 to eGFR SI units of mL/s/m^2 requires multiplication by 0.00963; conversion from creatinine clearance or eGFR conventional units of mL/min to SI units of mL/s requires multiplication by 0.0167; cystatin C in nmol/L can be converted to mg/L by multiplication using 0.01335 as the conversion factor.

CKD-EPI Equation

A single eGFR equation may not be best suited for all populations, and choice of equation has been shown to impact CKD prevalence estimates. The Chronic Kidney Disease Epidemiology Collaboration (CKD–EPI)[45] was developed to improve the accuracy of GFR estimates across the spectrum of kidney function. The CKD-EPI equation was developed from pooled study data involving 5,500 patients (including the original MDRD population), with mean GFR values of 68 ± 40 mL/min/1.73 m^2 (range 2-190 mL/min/1.73 m^2). The CKD-EPI equation is less biased (2.5 vs 5.5 mL/min/1.73 m^2) but similarly imprecise compared to MDRD4.[46] Specifically, the bias of the CKD-EPI equation is 61% to 75% lower than the MDRD equation for patients with eGFR of 60 to 119 mL/min/1.73 m^2.[46] Based on these findings, the CKD-EPI equation was deemed more appropriate for estimating GFR in individuals with eGFR values over 60 mL/min/1.73 m^2. National and international guidelines subsequently recommended that clinical laboratories switch from the MDRD4 to CKD-EPI equation for routine automated reporting.[2]

Kidney function values derived using eGFR equations may overestimate CG equation derived values for eCL_{cr} and thus may impact corresponding dosing recommendations. For example, use of MDRD-derived eGFR (expressed in mL/min) resulted in a failure to make manufacturer-recommended dose reductions for enoxaparin and the glycoprotein IIb/IIIa inhibitor (GPI) eptifibatide in up to 50% of patients. The eGFR-derived doses were correlated with major bleeding episodes (odds ratio 1.57 [95% CI 1.35-1.84]).[47] To date, use of eGFR for individualized drug dosing has not been comprehensively evaluated and automatic substitution of eGFR in place of eCLcr or mCL_{cr} for drug dose calculations should be avoided.

Cystatin C–Based Equations

Addition of serum cysC as a covariate in equations to estimate GFR has been employed as a means to improve creatinine-based estimations of GFR that historically were limited to the following variables; lean body mass (LM), age, sex, race, and S_{cr}.[48,49] Combining cysC and S_{cr} in the CKD-EPI equation improves precision and accuracy of GFR estimates across the range of GFRs.[49]

A significant limitation of serum cysC as a renal biomarker is the influence of body mass on serum concentrations. Fat-free mass is a significant covariate in GFR determination using cysC.[50,51] Using GFR measured as plasma inulin clearance, LM accounted for at least 16.3% of the variance in GFR values obtained using serum cysC. When using a serum cysC-based estimate of GFR, which incorporates the serum cysC, age, race, and sex, a higher prevalence of CKD was reported in obese patients compared to the MDRD4 equation.[51] Moreover, all-cause mortality rates may be significantly different between CKD-EPI and $\text{CKD-EPI}_{\text{cysC}}$ based estimates in older individuals. The CKD-EPI equation yields a U-shaped association, whereas the $\text{CKD-EPI}_{\text{cysC}}$ equation yields a linear relationship at eGFR values less than 60 mL/min/1.73 m^2, suggesting that cysC does not accurately predict mortality risk in older patients with low S_{cr}, reduced muscle mass, and malnutrition.[52] Because the combined use of serum cysC and serum creatinine in modified CKD-EPI equations generates improved estimates of GFR, the combined $\text{CKD-EPI}_{\text{Scr\_cysC}}$, equation (see Table e60-2) is recommended for use in patients where unreliable S_{cr} values are anticipated, such as extremes in body mass, diet, or creatinine assay interferences.[49]

A variety of online resources provide eGFR calculators to assist practitioners for the purpose of characterizing CKD stage. For example, NIH's NIDDK or the National Kidney Foundation websites provides an eGFR calculator using patient-specific data, with options to calculate eGFR using the MDRD4 or CKD-EPI equations. It should be noted that one must verify that a given equation is appropriate for the institutional creatinine reporting method.

Inclusion of a Race Coefficient in GFR Estimation

For over 20 years, GFR estimating equations used S_{cr}, age, sex (male or female), and race (Black or non-Black) to calculate an eGFR value. Originally, the race term in GFR estimating equations was found to improve equation accuracy since the mGFR was higher in people of African descent than Caucasian patients, and was meant to capture non-GFR determinants of S_{cr}.[53] Early work on the utility of eGFR equations in diverse ethnic groups resulted in modifications to them for use in some populations, including Japanese[54] and Chinese[55] populations. Recently, however, significant attention has been directed at addressing self-reported race as a social construct rather than a biological one. Since estimating equations that include a race coefficient use dichotomous response for Black race without regard to the proportion of a race or ancestry, and to reduce disparities in healthcare for Black individuals, many health systems began considering the use of alternative eGFR equations that do not require a race term.[53]

The potential implications of omitting race from eGFR equations that were originally developed with a race coefficient have been evaluated. Blending or removing race coefficients resulted in decreased eGFR estimates as well as increased reclassifications of CKD stage.[56] For example, if the race coefficient is removed from the original CKD-EPI equation, which was developed for use with a race coefficient, then the estimated CKD prevalence among US Black adults doubles. Additionally, removing the race coefficient could impact dose adjustment of medications in up to 40% of Black adults.[57]

Recently, new race-free eGFR equations using data from the CKD-EPI cohort were developed.[58] The new race-free eGFR creatinine-based equation underestimates mGFR in Black participants by 3.6 mL/min/1.73 m^2 with 87.2% of values falling within 30% of mGFR. The new eGFRcys equation overestimates mGFR in Black participants by 0.1 mL/min/1.73 m^2 with 84.6% of estimated values within 30% of mGFR. Lastly, the new combined eGFRcr-cys equation had the best performance with a bias of 0.1 mL/min/1.73 m^2 and 90.5% of estimated values within 30% of mGFR. An expert task force from the National Kidney Foundation and American Society of Nephrology (NKF-ASN) published recommendations for race-free equations that are now widely endorsed.[59] The NKF-ASN Task Force recommends use of the new eGFR equation based on creatinine that does not require a race term, for use in categorizing and staging CKD. The Task Force also recommends use of the combined creatinine-cystatin C–based eGFR equation once implementation barriers including widespread availability in clinical laboratories and reimbursement for cystatin C are removed.[59]

Estimation of Creatinine Clearance

⑦ Many equations describe the mathematical relationships between various patient factors and mCL_{cr}. Most equations incorporate factors such as age, gender, weight, and S_{cr}, without the need for urine collection. The most widely used estimate of creatinine clearance is the CG equation, which identified age and body mass as important covariates.[60] This was based on observations from 249 male patients with stable kidney function in whom the creatinine production rates were estimated. The CG based eCL_{cr} is calculated as follows[60]:

$$\text{Men}: CL_{cr} = [(140 - \text{age})\text{ABW}]/(S_{cr} \times 72)$$
$$\text{Women}: CL_{cr} \times 0.85$$

Men:CLcr=[(140–age)ABW]/(Scr×72)Women:CLcr×0.85

where ABW is actual body weight (kg), CL_{cr} is creatinine clearance in mL/min, and S_{cr} is serum or plasma creatinine (mg/dL). For SI conversion purposes serum creatinine is converted from µmol/L to mg/dL by multiplying by 0.0113. Conversion from creatinine clearance conventional units of mL/min to SI units of mL/s requires multiplication by 0.0167.

Estimated creatinine clearance (eCL_{cr}), using the CG equation, is one of the methods recommended by the FDA for stratifying patients in drug development pharmacokinetic studies,[3] and has been included most often in FDA-approved package inserts for new drug entities since the 1990s.[61]

One of the key considerations with the use of this equation is whether to use a modified weight index in place of actual body weight. Several modified weight indices have been proposed and this remains a controversial issue. For obese individuals, defined as those with a body mass index (BMI) greater than or equal to 30 kg/m^2 but less than 40 kg/m,[2] it is generally recommended that total or actual body weight be used. In morbidly obese individuals (BMI ≥40 kg/m,[2] obesity class III) an alternate measure of body weight such as lean body weight (LBW) reduces bias in the CG equation, where LBW is calculated as follows:

$$\text{LBW(kg, males)} = (9270 \times \text{weight})/(6680 + 216 \times \text{BMI})$$
$$\text{LBW(kg, females)} = (9270 \times \text{weight})/(8780 + 216 \times \text{BMI})$$

LBW(kg,males)=(9270×weight)/(6680+216×BMI)LBW(kg,females)=(9270×weight)/(8780+216×BMI)

and BMI is calculated as follows:

$$\text{BMI}\left(\text{kg/m}^2\right) = \text{weight(kg)}/\text{height(m)}^2$$

BMI(kg/m2)=weight(kg)/height(m)2

Regardless of the approach used to estimate kidney function in obese patients, it is imperative that drug therapy outcomes be monitored closely in this population.

ASSESSMENT OF KIDNEY FUNCTION IN SPECIAL POPULATIONS

Liver Disease

Evaluation of renal hemodynamics is particularly complicated in patients with liver disease and cirrhosis, where filtration fraction is associated with the degree of ascites, renal artery vasoconstriction, and vascular resistance.[62] The estimation of CL_{cr} or GFR can be problematic in patients with preexisting liver disease and renal impairment. Lower-than-expected S_{cr} values may result from reduced muscle mass, protein-poor diet, and diminished hepatic synthesis of creatine (a precursor of creatinine), and fluid overload. These lower S_{cr} values can lead to significant overestimation of CL_{cr}. In fact, CG may overestimate the mCL_{cr} by 40% to 100% in patients with severe liver disease.[63]

Cystatin-C based eGFR equations may be more accurate than eGFR equations based on creatinine alone in patients with advanced liver disease. The CKD-EPI$_{\text{cr-cysC}}$ equation is more precise than the CG, CKD-EPI, or CKD-EPI$_{\text{cystatin C}}$ when compared to iothalamate-mGFR.[64] The accuracy of the CKD-EPI$_{\text{cr-cysC}}$ equation, measured as percentage of eGFR that differs by more than 30% with respect to mGFR, and is significantly less than mCL_{cr}, CG, MDRD, and CKD-EPI$_{\text{creatinine}}$ equations. In summary, kidney function assessment in patients with hepatic disease should be performed by measuring glomerular filtration rate, and GFR estimation equations that combine creatinine and cystatin C are preferred.

Unstable Kidney Function

Patients with unstable kidney function or AKI present a unique situation because S_{cr} values are changing, breaking the underlying steady-state assumption of all the above-mentioned estimating equations. Methods to measure GFR include ^{125}I-iothalamate, ^{51}Cr-EDTA, or iohexol clearance. Moderately strong evidence suggests that renal clearance of ^{51}Cr-EDTA or iothalamate and plasma clearance of ^{51}Cr-EDTA or iohexol are sufficiently accurate methods to measure GFR.[65] Some of these methods are cumbersome and expensive, limiting their implementation in the clinical setting. Plasma clearance of iohexol is a simpler method that has been implemented in a few centers in the United States. However, it is unclear if this is being used for repetitive measures of kidney function as is frequently employed in AKI.

The CKD-EPI equations cannot be used in the critically ill population with unstable kidney function, because they require S_{cr} to be in steady state. The 1-hour mCL_{cr} correlates poorly with the CG and MDRD equations in critically ill patients.[66] Both equations are similarly imprecise with wide confidence intervals. The precision and accuracy of several estimating equations (CG, MDRD, CKD-EPI, CysC) is poor compared to a 4-hour mCLcr in ICU patients, showing suboptimal precision and a large bias.[67]

Equations for unstable kidney function include Jelliffe or kinetic GFR equations. The Jelliffe equation for unstable kidney function utilizes volume of distribution of creatinine and creatinine kinetics to estimate CL_{cr} and has less bias compared to other estimating equations in the critically ill population.[68] Adjusting the Jelliffe equation for fluid balance in AKI results in values closest to mCL_{cr}.[69] An alternative kinetic eGFR equation, which estimates GFR on the basis of initial creatinine content, volume of distribution, creatinine production rate, and the quantitative difference between consecutive S_{cr} in a defined time period is also available.[70] The kinetic eGFR has been applied in AKI to evaluate the impact on drug dosing. The concordance between CG and kinetic eGFR for drug dosing is only 62%, compared to 75% with MDRD and kinetic eGFR.[71] Others found a maximum discordance rate of 16.4% for drug dosing when comparing different estimating equations (CG, MDRD, Jelliffe, modified Jelliffe) to mCL_{cr} for antimicrobial dosing. When using CG or MDRD estimates, the drug doses were all higher compared to modified Jelliffe eGFR.[72] It is anticipated that using the modified Jelliffe or kinetic eGFR in place of steady-state estimating equations will result in different drug dosing recommendations in AKI and careful consideration of the risk:benefit of each dosing regimen is warranted.

The Acute Disease Quality Initiative (ADQI) group published a consensus report on acute kidney disease and renal recovery where they recommend that additional research is needed to validate the use of non-steady-state estimating equations in AKI.[73] Their current recommendation is for the use of timed mCLcr in the setting of persistent AKI which is in steady state.[73]

Children

Neonatal kidney function is difficult to assess because of challenges in the collection of urine and blood samples, the frequent presence of a non-steady-state S_{cr}, maternal placental transfer of creatinine early after birth, and apparent disparity between development of glomerular and tubular function. Preterm infants demonstrate significantly reduced GFR prior to 34 weeks, which rapidly increases to that of term infants within the first week of life.[74] Thus, estimation of GFR is not recommended for infants younger than 1 week. Kidney function expressed as GFR standardized to body surface area (BSA) increases with age and stabilizes at approximately 1 year. In older children, GFR is best assessed using standard measurement techniques for GFR. Subcutaneous administration of ^{125}I-iothalamate has been effectively used to measure GFR in children ranging in age from 1 to 20 years.[75] The Schwartz equation[76] was developed from a population of 349 children (1-19 years) with mild-to-moderate CKD enrolled in the Chronic Kidney Disease in Children (CKiD) study. This simple equation is commonly referred to as the Schwartz "Bedside" formula:

$$\mathrm{eGFR}_{\mathrm{CKiDbed}} = 41.3 * [\mathrm{height\ (m)}/\mathrm{S_{cr} in mg/dL}]$$

eGFRCKiDbed=41.3*[height (m)/Scrinmg/dL]

For SI conversion purposes serum creatinine is converted from µmol/L to mg/dL by multiplying by 0.0113. Schwartz et al.[77] developed another equation, CKiD full equation, adding cysC measurements in addition to Scr, and found high accuracy and precision and minimal bias in the CKiD population. For SI conversion purposes serum urea is converted from mmol/L to mg/dL by multiplying by 2.801, and serum cystatin C is converted from nmol/L to mg/L by multiplying by 0.01335.

$$\mathrm{eGFR}_{\mathrm{CKiDfull}} = 39.8 \times (\mathrm{height[m]/Scr[mg/dL]})^{0.456} \times (\mathrm{1.8/cystatinC[mg/L]})^{0.418} \times \\ (\mathrm{30/SUN[mg/dL]})^{0.079} \times 1.076(\mathrm{ifmale}) \times (\mathrm{height[m]}/1.4)^{0.179}$$

eGFRCKiDfull=39.8×(height[m]/Scr[mg/dL])0.456×(1.8/cystatinC[mg/L])0.418×(30/SUN[mg/dL])0.079×1.076(ifmale)×(height[m]/1.4)0.179

Older Adults

Generally, GFR is considered to decline as a function of age. The Baltimore Longitudinal Study on Aging (BLSA) showed that mCL_{cr} decreases at the rate of approximately 0.75 mL/min/1.73 m^2/yr (0.0072 mL/s/m^2/yr) beginning at the fourth decade of life.[78] Interestingly, after up to 23 years of follow-up, approximately one-third of the participants showed no change in kidney function from their baseline value, and a small number showed an increased clearance.[78] These changes may be a result of normal physiologic changes or of subclinical insults to the kidneys initiating the events leading to chronic progressive loss of kidney function.

Interpretation of S_{cr} alone is difficult in older adult patients primarily because of decreased muscle mass and the resultant lower production rate of creatinine. Thus, the S_{cr} often remains within the normal range despite a reduction in the number of functional nephrons. The adoption of standardized creatinine assays by clinical laboratories and reporting of S_{cr} values to two decimal places will likely improve the accuracy of kidney function estimation in older adults.

The CG formula provides a valid estimate of CL_{cr} in older populations.[60] In an analysis of the BLSA data set, the CG equation yielded the least biased estimate of mCl_{cr}, whereas the MDRD4 and CKD-EPI equations significantly overestimated the CG and mCl_{cr} values by 30% to 47%.[79] Rounding low S_{cr} values up to an arbitrary value of 1.0 mg/dL (88 µmol/L) result in CG values that significantly underestimate mCl_{cr} and uncorrected CG. The commonly accepted practice of fixing or rounding S_{cr} to an arbitrary value in older patients should be avoided.

IMPACT ON DRUG DOSING RECOMMENDATIONS

The automated reporting of eGFR in the clinical setting has led some practitioners to consider substituting eGFR in place of eCL_{cr} for drug dose adjustments as recommended in regulatory agency–approved product labeling. The prime concern with this approach, particularly in older adults, is that substitution of eGFR values in CL_{cr}-based dosage adjustment algorithms may result in dosing errors and toxicity especially for drugs with narrow therapeutic indices since eGFR tends to overestimate eCL_{cr}. For instance, MDRD eGFR values overestimate gentamicin clearance by up to 29%, whereas the CG CL_{cr} yields only 10% overestimation, and MDRD overestimates kidney function more as age increases.[80] Although use of an eGFR value (MDRD4 equation in mL/min based on a calculated BSA) yields dosage regimens for a subset of drugs that are similar to doses calculated using mGFR,[81] overestimation of kidney function using the MDRD4 equation may result in up to 30% to 60% higher doses for digoxin, amantadine, and various antimicrobials compared to doses calculated using eCL_{cr}.[82,83] It must be cautioned that use of eGFR in place of eCL_{cr} for drug dose adjustments does not align with the majority of drug development studies (and as reported in the product label) for FDA-approved drugs currently marketed. Moreover, although dosing concordance between eGFR and eCL_{cr} based estimates is high, drug dosing based on eGFR can lead to clinically significant dosing errors for drugs such as eptifibatide, tirofiban, and enoxaparin and in high-risk older adult populations.[84,85]

Use of modified eGFR and newer CKD-EPI equations including race free estimates to adjust drug doses has also been reported, but not fully validated. For example, the deindexed $\text{CKD-EPI}_{\text{cr-cysC}}$ equation (converted to mL/min) yields a 2.5-fold improvement in achieving target vancomycin trough values in critically ill patients, when compared to eCL_{cr}.[86] Of note, predicted trough values improve among those with normal GFR (greater than 120 mL/min [2 mL/s]), where underdosing is often problematic. Future areas yet to be fully evaluated include use of newer eGFR equations and deindexing values for drug dosing. A more detailed discussion of the utilization of kidney function estimates and renal dosing approaches is provided in Chapter 67, Personalized Pharmacotherapy for Patients with Chronic Kidney Disease.

MEASUREMENT OF RENAL PLASMA AND BLOOD FLOW

While rare in the clinical setting, renal plasma and blood flow are occasionally measured in research settings to evaluate hemodynamic changes related to disease or drug therapy. The kidneys receive approximately 20% of cardiac output. Representative values of renal blood flow in men and women are about 1,200 mL/min/1.73 m^2 and 1,000 mL/min/1.73 m^2 (11.6 and 9.6 mL/s/m^2), respectively. Renal plasma flow (RPF) is estimated to be

60% of blood flow assuming that the average hematocrit (HCT) is 40% (0.40) and that it can be measured by the use of model compounds that are eliminated from the plasma compartment on a single pass through the kidneys. Para-aminohippuric acid (PAH) is an organic anion that has been used extensively for the quantification of RPF. PAH is approximately 17% bound to plasma proteins and is eliminated extensively by active tubular secretion. Because PAH elimination is active, saturation of the transport processes should be anticipated, and concentrations of PAH in plasma should not exceed 10 mg/L.[87] The extraction ratio (ER) for PAH is 70% to 90% at plasma concentrations of 10 to 20 mg/L; hence, the term “effective” renal plasma flow (ERPF) has been used when the clearance of PAH is not corrected for the ER or if it is assumed to be 1. Normal values are about 650 mL/min (10.9 mL/s) for men and 600 mL/min (10.0 mL/s) for women. Children will reach normalized adult values by 3 years of age, and ERPF will begin to decline as a function of age after 30 years, reaching about one-half of its peak value by 90 years. The method for calculation of ERPF is based on the relationship between organ clearance, ER, and flow:

$$\mathrm{ERPF} = \mathrm{renalPAHCL} = \mathrm{RPF} \times \mathrm{ER}$$

ERPF=renalPAHCL=RPF×ER

Effective renal blood flow (ERBF) can be estimated from ERPF by assuming the extraction ratio is 1 and correcting for the red blood cell volume of the blood (HCT):

$$\mathrm{ERBF} = \mathrm{ERPF}/(1 - \mathrm{HCT})$$

ERBF=ERPF/(1−HCT)

ASSESSMENT OF TUBULAR FUNCTION

Although GFR is the best overall indicator of kidney function, it may not provide an accurate measure of tubular function (either secretory capacity or cellular function) suitable for use in the research environment. Since renal tubular function is directly related to renal blood flow, tubular secretion can be measured using surrogate markers such as PAH, as described above. Other compounds that are substrates for the organic cationic transporter (OCT) such as N^1-methylnicotinamide (NMN) and tetraethylammonium may be used as markers of cationic secretory capacity.

Semi-quantitative measures of tubular function are more widely used in clinical settings, focusing on detection of tubular injury within the nephron. Low-molecular-weight proteins located in the proximal tubule, such as β_2-microglobulin, can be used as urinary biomarkers to detect early tubular toxicity of some drugs including carboplatin, ifosfamide, and etoposide.[88] Other low-molecular-weight proteins used as markers of tubular function include retinol-binding protein (21 kDa), protein HC (also known as α_1-microglobulin, 27 kDa), KIM-1, NGAL, interleukin-18, and fatty-acid binding proteins (FABPs).[89] Under normal conditions, these proteins are freely filtered at the glomerulus and then completely reabsorbed by the proximal tubule. In the presence of tubular injury, these enzymes are increasingly excreted and appear in the urine. Although suggestive of tubular pathology, they are not entirely specific. For example, increased excretion could be due to an overload of the maximal reabsorptive capacity, leading to net excretion of the protein.

Examples of other biomarkers used to detect early renal tubular damage include *N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ-glutamyltransferase, pyruvate kinase, glutathione transferase, lysozyme, and pancreatic ribonuclease. *N*-acetylglucosaminidase and alanine aminopeptidase may be early predictors of early renal allograft rejection in kidney transplant patients.[90] *N*-acetylglucosaminidase is an enzyme contained within the lysosome of the tubular cell and is released when the lysosome is damaged, whereas alanine aminopeptidase is an enzyme of the brush border. Both markers are increased approximately 2 days earlier than S_{cr} in patients with transplant rejection. Other biomarkers associated with fibrosis and collagen degradation in the kidney such as matrix metalloproteinases (ProMMP9) may also be associated with acute allograft rejection, interstitial fibrosis, and tubular atrophy.[91]

QUALITATIVE DIAGNOSTIC PROCEDURES

Radiologic Studies

⑦ The etiology of kidney disease can be evaluated using several qualitative diagnostic techniques, including radiography, ultrasonography, magnetic resonance imaging, and biopsy.[92] The standard radiograph of the kidneys, ureters, and bladder (the KUB) provides a gross estimate of kidney size and identifies the presence of calcifications. Although easy to perform, the value of the information is minimal, and more detailed evaluations are often necessary. The *IV urogram* (formerly known as IV pyelogram) involves the administration of a contrast agent to facilitate visualization of the urinary collecting system. It is primarily used in the assessment of structural changes that may be associated with hematuria, pyuria, or flank pain, resulting from recurrent urinary tract infections, obstruction, or stone formation. For patients with low GFRs, retrograde administration of dye into the ureters may be performed to facilitate visualization of the collecting system. Contrast agents are also employed during renal angiography for the assessment of renovascular disease. The captopril (angiotensin-converting enzyme inhibitor) test is also a useful adjunct. Under conditions of unilateral renal artery stenosis, the affected kidney produces large quantities of angiotensin II, which constricts the efferent arteriole to maintain GFR. The administration of captopril results in reduced uptake of the contrast agent because the efferent arteriole is dilated, thereby decreasing the perfusion pressure of the affected kidney. For patients with bilateral disease, a decrease in uptake is observed in both kidneys. Computed tomography is a cross-sectional anatomic imaging procedure. The procedure is frequently performed with contrast to enhance imaging. Spiral, or helical, computed tomography provides for three-dimensional visualization of tissues. Computed tomography is performed as a test for the evaluation of obstructive uropathy, malignancy, and infections of the kidney.

Renal Ultrasonography

Ultrasonography uses sound waves to generate a two-dimensional image. Evaluation includes assessment of shape and size, echogenicity, the urinary space (including the lower urinary tract), vasculature, and presence of masses.[92] The echogenicity of the kidney is compared with that of an adjacent organ—liver on the right and spleen on the left—with an increased echogenicity indicating an abnormal finding. Ultrasonography can distinguish the renal pyramids, medulla, and cortex, and abnormalities in structure, such as occurs with obstruction. Renal ultrasonography is also used as a guide for site localization during percutaneous kidney biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging is based on aligning hydrogen nuclei in the body with the use of a powerful magnet and applying radiofrequency pulses. The signals emitted by the hydrogen nuclei during realignment on repeated pulses allows for generation of the tissue image. Realignment times can also be altered with the use of contrast agents (gadolinium, gadopentetate), leading to increased signal intensity and improved imaging. Magnetic resonance imaging is useful for the assessment of obstruction, malignancy, and renovascular lesions.

Biopsy

Renal biopsy is used in several situations to guide diagnosis, evaluate progression, and support clinical decision making when clinical, laboratory, and imaging findings do not suffice. Proteinuria and hematuria are both associated with renal parenchymal disease. When less-invasive studies are unsuccessful in differentiating the cause and the possible causes have different therapeutic approaches, biopsy may be indicated. Functional status of the kidney is not assessed with biopsy, and severity of disease and progression is best measured using quantitative tests discussed above. Contraindications to renal biopsy include a solitary kidney, severe hypertension, bleeding disorder, severe anemia, cystic kidney, and hydronephrosis, among others. Complications resulting from biopsy primarily include hematuria, which may last for several days, and perirenal hematoma.

CONCLUSION

Approaches to evaluate kidney function in CKD patients include the CG equation for estimating CL_{cr}, various CKD-EPI equations for estimation of GFR, and determination of UACR as a marker of the integrity of the glomerular basement membrane. Measurement of GFR using exogenous administration of iothalamate, iohexol, or radioisotope techniques such as ^{99m}Tc-DPTA is increasingly being employed to assess progression of disease or acceptability of an individual to be a kidney donor. Other qualitative assessments of kidney function, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are most useful to identify the underlying cause of kidney disease.

ABBREVIATIONS

AASK	African American Study of Kidney Disease and Hypertension
ABC	ATB-binding cassette

ADP	adenosine diphosphate
AKI	acute kidney injury
ATP	adenosine triphosphate
AUC	area under the plasma concentration versus time curve

SELF-ASSESSMENT QUESTIONS

1. The glomerulus is primarily responsible for ___ of unbound drug in the kidney.

    A. filtration

    B. reabsorption

    C. secretion

    D. endocytosis

2. Active drug secretion occurs most often in which of the following nephron segments?

    A. Glomerulus

    B. Proximal tubule

    C. Loop of Henle

    D. Distal tubule

3. Which of the following is/are involved in drug influx at the basolateral membrane of the proximal tubule?

    A. OAT1-3

    B. OCT1-3

    C. OAT4

    D. Both A and B

4. According to the intact nephron hypothesis, single nephron GFR ___ in the surviving nephrons.

    A. decreases

    B. increases

    C. remains the same

5. The kidney is responsible for synthesizing each of the following hormones, *except*:

    A. Erythropoietin

   B. Prostaglandin
   C. PTH
   D. Renin

6. Which of the following kidney function indices is most influenced by changes in fluid or volume status?
   A. Serum creatinine
   B. Blood urea nitrogen
   C. Urine specific gravity
   D. Urine albumin to creatinine ratio

7. Which of the following kidney function indices is least affected by dietary protein intake?
   A. Serum creatinine
   B. Blood urea nitrogen
   C. Creatinine clearance
   D. Urine sodium

8. Which is the most appropriate method to quantify proteinuria in a patient with CKD risk factors such as diabetes?
   A. Spot or random urine total protein:creatinine ratio
   B. Spot or random urine albumin:creatinine ratio
   C. 24-hour urine protein excretion
   D. Urinalysis

9. Which of the following equations is most appropriate for estimating a patient's GFR for the purpose of determining their CKD category/stage?
   A. MDRD equation
   B. CKD-EPI$_{\text{creatinine}}$ equation
   C. CKD_cysC equation
   D. Cockcroft–Gault equation

10. When using the Cockcroft–Gault equation to estimate creatinine clearance in obese patients, it is recommended that lean body weight be used in patients with:
   A. BMI ≥40 kg/m^2
   B. BMI 30-39 kg/m^2
   C. BMI 25-29 kg/m^2
   D. None of the above

11. J.S. is a 70-year-old male of African American ancestry (5 ft 8 in. [173 cm], 85 kg) with a history of hypertension and CKD. His serum creatinine today

is 1.50 mg/dL (133 µmol/L) (using the IDMS calibrated assay). What is his estimated creatinine clearance?

   A. 55.0 mL/min

   B. 43.5 mL/min

   C. 37.2 mL/min

   D. 29.4 mL/min

12. What is J.S.'s estimated GFR (in mL/min/1.73 m^2)?

   A. 50 mL/min/1.73 m^2

   B. 45 mL/min/1.73 m^2

   C. 35 mL/min/1.73 m^2

   D. 30 mL/min/1.73 m^2

13. What is J.S.'s estimated GFR when expressed in mL/min?

   A. 50 mL/min

   B. 53 mL/min

   C. 55 mL/min

   D. 57 mL/min

14. Progression to end-stage kidney disease can be estimated using all the following *except*:

   A. Age

   B. Urinary albumin:creatinine ratio

   C. Urinary cystatin C concentration

   D. Estimated GFR

15. In the clinical setting, the renal clearance of PAH is considered an index of ____.

   A. fractional excretion of sodium

   B. renal plasma or blood flow

   C. glomerular filtration rate

   D. renal tubular reabsorption

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** The glomerulus is the primary filtering unit in the kidney.

2. **B.** Secretion is an active process taking place in the proximal tubule and facilitates the elimination of compounds from kidney circulation into the tubular lumen.

3. **D.** OAT1-3 and OCT1-3 are influx transporters known to be involved in transport of drugs into the proximal tubule.
4. **C.** In kidney disease, the remaining intact nephrons hyperfilter to maintain the total GFR.
5. **C.** PTH is produced by the parathyroid gland.
6. **C.** Urine specific gravity would be most influenced by volume status. The urine albumin to creatinine ratio would be less influenced since urine concentration impact is in the numerator and denominator of the ratio.
7. **D.** Urine sodium is not impacted by dietary protein intake but would be impacted by dietary sodium intake or use of diuretics.
8. **B.** The random UACR is a sensitive test for quantifying proteinuria in early kidney disease (ie, stage 1-2, where GFR is intact or mildly reduced) in at-risk patients.
9. **B.** The CKD $\text{EPI}_{\text{creatinine}}$ equation is used by most laboratories to estimate GFR for the purpose of staging CKD.
10. **A.** Lean body weight should be used when the BMI is greater than 40 kg/m^2, which is considered morbid obesity.
11. **A.** The Cockcroft–Gault equation is used to estimate creatinine clearance. This patient has a BMI of 28.4 which is considered overweight, but actual body weight should be used to calculate his clearance.
12. **A.** The CKD $\text{EPI}_{\text{creatinine}}$ 2021 equation should be used to estimate GFR and does not require a race term.
13. **D.** The CKD EPI 2021 equation should be used to estimate GFR and when adjusting for his BSA, the estimate is higher at 57 mL/min.
14. **C.** Urinary cystatin C concentrations are not used in estimating progression of kidney disease. Serum cystatin C concentrations may be used to estimate GFR in addition to Scr.
15. **B.** PAH clearance is used to measure renal blood flow.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter e66: Glomerular Diseases

Duncan B. Johnstone

KEY CONCEPTS

KEY CONCEPTS

① Glomerular diseases vary in causes, clinical symptoms, treatments, and outcomes, but are united because they all affect the glomerulus, which is the filter of the kidney.

② The five principal clinical features of glomerular disease are hematuria, proteinuria, edema, hypertension, and progressive kidney failure. These features occur to varying degrees among different glomerular diseases and between individual patients.

③ Glomerular diseases can be classified with many different systems, each of which has advantages and disadvantages. A basic classification is whether a glomerular disease is nephritic (reflecting inflammatory injury) or nephrotic (reflecting noninflammatory injury).

④ For some glomerular diseases there are treatments that can induce a remission, which is often based on suppression of the immune system. If disease remission cannot be achieved, we use conservative measures to reduce proteinuria, edema, hypertension, hyperlipidemia, and hypercoagulability, with the aim of stabilizing the loss of kidney function.

⑤ Patients undergoing treatment for glomerular disease must be monitored closely to assess their therapeutic response and any treatment-induced toxicity.

⑥ Among all glomerular diseases, minimal-change nephropathy is the most responsive to treatment with steroids.

⑦ Focal segmental glomerulosclerosis (FSGS) is difficult to treat for two reasons: first, it is difficult to distinguish primary FSGS, which may respond to steroids or other immunosuppressants, from the many causes of secondary FSGS, which will not respond to these treatments; second, the response of primary FSGS to steroids, unlike minimal change disease, is not robust.

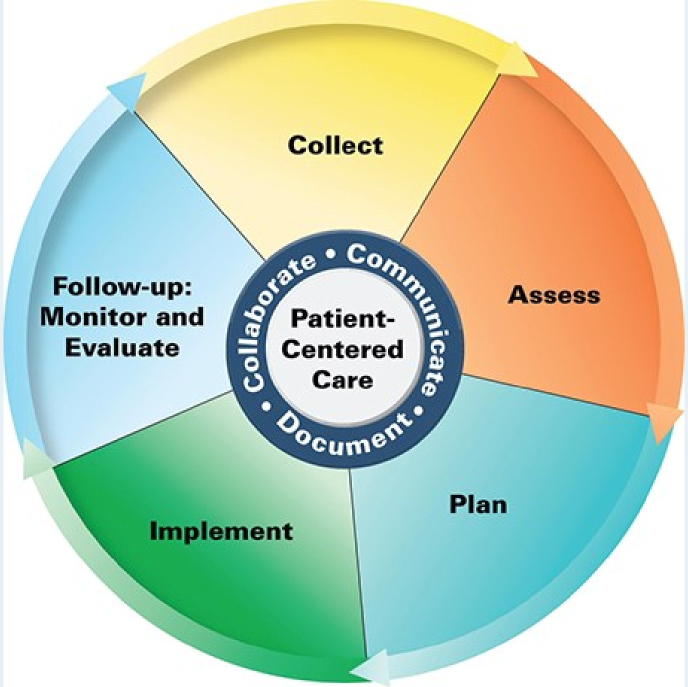
⑧ Systemic lupus erythematosus can cause many different types of kidney disease. The optimal treatment of lupus nephritis depends on the underlying lesion, the disease activity on biopsy, and the patient’s symptoms in organs other than the kidney.

⑨ Post-streptococcal glomerulonephritis arises when the immune response to bacteria damages the glomerular filter. By definition, post-streptococcal glomerulonephritis occurs after the infection, so there is no role for antibiotic therapy. Symptoms are treated aggressively with conservative measures.

⑩ Membranous nephropathy can be either primary disease, or secondary to a long list of other causes. Within the last 10 years, the cause of primary membranous nephropathy has been identified as auto-antibodies to the phospholipase A2 receptor, resulting in significant improvements in diagnosis, treatment, and outcomes.

PATIENT CARE PROCESS

Patient Care Process for Managing Glomerular Disease



Collect

Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, ethnicity)
- History of present illness (eg, edema, gross hematuria, extra-renal symptoms such as hemoptysis and joint pains)
- Patient medical history (personal and family) (see Table e66-2)
- Social history (eg, tobacco use, history of drug use) and dietary habits including sodium intake
- Current medications including OTC NSAID use and blood pressure medications
- Objective data (see Table e66-2)
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Labs including serum creatinine (SCr), serum albumin, complete blood count, urinalysis, random urine protein:creatinine ratio, and urine microscopy
    - May consider a limited serologic workup (eg, complement component C3 and C4 levels, anti-nuclear antibody, anti-phospholipase A2 receptor antibody)
    - Renal ultrasound

Assess

- Blood pressure (goal generally <130/80 mm Hg)
- Volume status for presence of peripheral edema, pulmonary edema, hypertension.
- Presence of life-threatening complications such as pulmonary hemorrhage and venous thromboembolism

- Ability to monitor weights and blood pressures at home
- Ability to tolerate immunosuppressive therapy such as corticosteroids (potential risk of steroid-induced diabetes, infections, weight gain, bone disease, and mania)
- Ability to pay for treatments

Plan*

- Blood pressure control with angiotensin converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs)
- Volume control (edema +/− hypertension) with diuretics (see Table e66-3)
- Home monitoring of blood pressure and weight
- Immunosuppressive therapy if indicated
- Regular lab monitoring
- Patient education
- Referral to other providers, when applicable

Implement*

- Provide patient education regarding all elements of treatment and follow-up plan
- Schedule follow-up labs and clinic visits

Follow-up: Monitor and Evaluate

- Achievement of remission (definition depends on type of glomerular disease)
- Achievement of blood pressure and volume control (see Table e66-3)
- Taper/discontinue immunosuppressive medications when applicable
- Monitor for adverse events of treatment

***Collaborate with patient, caregivers, and other healthcare professionals.**

BEYOND THE BOOK

BEYOND THE BOOK

Visit the National Kidney Foundation website <https://www.kidney.org>. This website is useful to learn about kidney disease from the perspective of both patients and healthcare providers. Watch the video titled “New Insights Regarding Treatment of Membranous Nephropathy” at <https://www.kidney.org/content/new-insights-regarding-treatment>. This video provides an overview of the approach to treating membranous nephropathy, particularly with regards to immunosuppressive therapy, and is useful to enhance student understanding regarding the ASSESS and PLAN steps in the patient care process.

INTRODUCTION

Glomerular disease is one of the most common causes of end-stage kidney disease (ESKD). From the 2018 yearly report of all patients nationwide by US Renal Data Systems, the number of patients who started dialysis that year (incident patients) was 213,588, of whom 7% carried a diagnosis of primary glomerular disease.[1] This under-represents the total burden of glomerular disease because this figure of 7% does not include secondary glomerular diseases such as classic diabetic nephropathy, does not include patients starting dialysis due to undiagnosed glomerular disease that was erroneously labeled “hypertensive nephropathy,”[2] and does not include patients with “ESKD of unknown cause,” who never had a biopsy, some of whom likely had glomerular disease. Altogether, if we combine primary, secondary, and undiagnosed glomerular diseases, we account for about 40% to 60% of new ESKD patients starting dialysis each year, which is roughly 100,000 people. A larger number of patients with glomerular disease are receiving treatment and trying to avoid progression of their disease to ESKD.

The aim of this chapter is to introduce clinicians to the general principles of glomerular disease, and then to highlight the characteristics of some of the most common glomerular disorders. Diabetic nephropathy is the most common glomerular disease in the United States and worldwide and is presented in Chapter 94. Nevertheless, the general principles of glomerular disease discussed in this chapter also apply to diabetic glomerular disease.

NORMAL GLOMERULAR ANATOMY AND FUNCTION

Evaluation, diagnosis, and treatment of glomerular disease is complex, because each glomerular disease differs from the next, and has such a wide variety with a given disease, including variations in cause, clinical severity, and histopathology on kidney biopsy, organ involvement and treatment, that the nuance and detail can become overwhelming. To simplify, there is a unifying feature to all glomerular diseases, which can be appreciated by considering the kidney as an organ that performs two basic functions: (1) the kidneys filter blood, making about 170 L of filtrate very day, which can be thought of a “raw urine,” and (2) renal tubules reabsorb about 168 L of this filtrate, which includes valuable salt water and small molecules like glucose and amino acids. The renal tubules then fine tune the composition and amount of water to make our “final urine,” which is ready for excretion. With these two basic functions in mind, the unifying feature of all glomerular diseases is that they disrupt the first of these, the filtration of blood.

As a starting point, consider the similarities between glomerular filtration and making a pot of coffee, with coffee grounds on top, then a coffee filter, and then water being forced from top to bottom by gravity to make a filtrate of coffee. With glomerular filtration, instead of coffee grounds on top, we have blood, which includes plasma, red and white blood cells, and serum proteins. Instead of a coffee filter preventing coffee grounds from entering the coffee pot, we have a glomerular filter preventing cells and serum proteins from passing through into the filtrate. And instead of a filtrate of coffee, the glomerular filtrate is about 170 L of “raw urine” as mentioned above. If we were to poke holes in a coffee filter with a pencil, coffee grounds would leak through into our filtrate of coffee. Similarly, if molecular holes are poked in the glomerular filter, red blood cells and serum proteins will leak through into the urinary filtrate. In this regard, blood cells and serum proteins that have leaked through the filter and into urine are the cardinal features of glomerular disease.

After this, the analogy breaks down. Instead of having one coffee filter, each kidney normally contains 500,000 to 600,000 glomerular filters, or just over 1 million glomeruli per person. Glomeruli are located within the outer shell of the kidney, which is called the cortex. There are no glomeruli within the inner shell of the kidney, which is called the medulla. Each glomerulus is a sphere, with a vascular pole on one side of the sphere. At this vascular pole, blood enters the glomerulus via an afferent arteriole, flows through a single tube called the glomerular capillary, which is bunched up inside the glomerulus into loops and then blood exits the glomerulus via an efferent arteriole (**Fig. e66-1**).

FIGURE e66-1

Components of the nephron. Each nephron originates in the cortex, at the renal corpuscle surrounding a small tuft of glomerular capillaries. Extending from the corpuscle is the proximal convoluted tubule, which leads to the proximal straight tubule that enters the outer medulla. This tubule continues as the thin descending limb and the thin ascending limb of the nephron’s loop of Henle in the medulla. The loop of Henle ends with a thick ascending limb, a straight tubule that reenters the cortex and ends at its thickened macula densa area where it contacts the arterioles entering the glomerulus. Beyond the macula densa this tubule is the distal convoluted tubule, the end of which is the short connecting tubule. Connecting tubules from many nephrons merge into cortical collecting tubules and a collecting duct. (Reproduced, with permission, from Mescher AL. Junqueira’s Basic Histology: Text & Atlas. 16th ed. Within the glomerular capillary, blood plasma is filtered across a semi-permeable membrane by hydrostatic pressure of about 20 to 30 mm Hg, which is a uniquely high blood pressure compared to all other capillaries in our body. On the other side of the membrane, the filtrate that is formed within Bowman's space exits the glomerulus at the urinary pole and enters the first portion of the proximal tubule. Glomerular capillary loops are supported by a matrix of cells and interstitial tissue called the mesangium, which extends from the vascular pole into the center of the glomerular sphere, and which provides support to each of the glomerular capillary loops. Both the filtrate and blood that leave a particular glomerulus remain linked biologically. Filtrate from a particular glomerulus exits at the urinary pole and enters the first segment of the proximal tubule, while blood exits the glomerulus via the efferent arteriole and forms a network of capillaries to supply blood to the proximal tubule of the very same glomerulus. This linkage allows a single nephron to sense what it's glomerulus has filtered (by sampling sodium and chloride flow in the filtrate) and if a glomerulus is filtering excessively, to decrease blood supply to that glomerulus in a process called tubulo-glomerular feedback. Tubulo-glomerular feedback is an important part of the pathophysiology and treatment of several glomerular diseases.

As blood plasma crosses the glomerular filter to make a urinary filtrate, higher resolution reveals that the filter is composed of three layers (**Fig. e66-2**). The first layer is the endothelium, which has large pores called fenestrae that are lined with anionic polysaccharides. The pore size and negatively charged polysaccharides exclude blood cells and probably large lipoprotein complexes from crossing into Bowman's space, but the pores are too large to exclude plasma proteins. The second layer is the glomerular basement membrane (GBM), which is a gel of negative charged proteins that are excreted into the extracellular space by glomerular endothelial cells on one side and the glomerular visceral epithelial cells (or podocytes) on the other side. The major protein component of the GBM is type IV collagen, which forms trimeric strands (like weaving a bracelet from three threads) out of three different protein subunits (alpha-3, alpha-4, alpha-5), each encoded by a separate gene. Type IV collagen trimers are then crosslinked into a web by other anionic proteins, resulting in a tight, proteinaceous gel full of negative charges. The third layer of the glomerular filter is formed by podocytes, which cover the GBM except at narrow filtration pores, also called slit diaphragms, that permit water, electrolytes and small molecules through but exclude large molecules. Podocyte cover the outer surface of glomerular loops like an octopus family, but with hundreds of arms. These podocyte arms are called foot processes, which interdigitate with foot processes of a neighboring podocyte (**Fig. e66-2**).

FIGURE e66-2

(*A*) The renal corpuscle consists of a small mass of capillaries called the glomerulus, housed within a glomerular capsule. The visceral layer of the capsule is composed of complex epithelial cells called podocytes, which cover each capillary, forming slit-like spaces between interdigitating processes called pedicels. Blood enters and leaves the glomerulus through the afferent and efferent arterioles, respectively. (*B*) The micrograph shows the major histologic features of a renal corpuscle. The glomerulus (G) of capillaries is surrounded by the capsular space (CS) covered by the simple squamous parietal layer (PL) of Bowman capsule. Near the corpuscle is that nephron's macula densa (MD) and sections of proximal convoluted tubules (PCT) and distal convoluted tubules (DCT). (*C*) Filtrate is produced in the corpuscle when blood plasma is forced under pressure through the capillary fenestrations, across the filtration membrane or GBM surrounding the capillary, and through the filtration slit diaphragms located between the podocyte pedicels. (*D*) The scanning electron microscopy (SEM) shows the distinctive appearance of podocytes and their pedicel processes that cover glomerular capillaries. Working together, the three layers of the glomerular filter create a semi-permeable membrane with both size and charge selectivity: small molecules like sodium pass through the filter freely, while molecules of increasing size do not. In addition, molecules that are negatively charged (anionic) are prevented from filtration by negatively charged GBM, whereas molecules that are positively charged (cationic) can cross the filtration barrier more easily. **Figure e66-3** illustrates how the filtration fraction falls based on molecular size and charge. Filtration fraction is the concentration of a molecule on the far side of the filter within Bowman's space divided by the concentration on the near side of the filter within a glomerular capillary. Small molecules like sodium that easily pass through the glomerular filter have a filtration fraction of 1.0, whereas larger molecules have an increasingly small filtration fraction. Discussions of glomerular disease often focus on albumin, which is by far the predominant protein in blood serum. Albumin is a moderately large protein with many negative charges, so in normal circumstances its filtration fraction is very low.

FIGURE e66-3

(A) As molecular weight (and therefore size) increases, filterability declines, so that proteins with a molecular weight above 70,000 Da are minimally filtered. (B) For any given molecular size, negatively charged molecules are restricted more than neutral molecules, while positively charged molecules are restricted less. While the three layers of the glomerular filter work together, each layer can be a separate target for glomerular disease. For instance, the first layer of the glomerular filter is the target of damage with preeclampsia. The second layer of the filter is the target for both Alport's disease, which arises from hereditary mutations of type IV collagen, and also Goodpasture's disease (anti-GBM nephritis), in which autoantibodies attack subunits of type IV collagen. The third layer of the filter, the podocytes, is the direct target for glomerular diseases such as focal segmental glomerulosclerosis (FSGS) and membranous nephropathy. The mesangium, in addition to recirculating components of the GBM, provides structural support to glomerular capillary loops, and can synthesize and respond to various cytokines. Mesangial cells are a target for several glomerular diseases including immunoglobulin A (IgA) nephropathy and diabetic nephropathy.

GLOMERULAR DISEASE PATHOPHYSIOLOGY AND HISTOLOGY

Glomerular diseases are classified in many ways. Each classification scheme tells us something important about the disease. The classical division of glomerular disease is based on whether or not inflammation is present on kidney biopsy. If inflammation is present, a pathologist will describe the location, such as the mesangium (as seen with IgA nephritis) or inside the glomerular capillary wall (as seen with endocapillary proliferation from lupus nephritis), or within Bowman's space (as seen with crescentic glomerulonephritis from ANCA+ vasculitis). Noninflammatory injury is recognized by damage or alteration of the glomerulus in the absence of inflammation, such as the presence of fibrosis seen on light microscopy (also described as sclerosis), or changes to the structure of the glomerular filter that are seen on electron microscopy, such as thickening of the glomerular basement membrane, or alternations of podocyte foot processes. With both inflammatory and noninflammatory glomerular injury, the appearance on kidney biopsy is divided into whether the disease appears "diffuse" (greater than 50% of all glomeruli in the biopsy are affected) or "focal" (less than 50% of glomeruli are affected), and for each glomerulus, whether the disease is "segmental" versus "global" (part of one glomerulus is affected vs the entire glomerulus). For both inflammatory and noninflammatory injury, fibrosis or sclerosis has good (but not perfect) prognostic value because for almost every glomerular disease, the percentage of tubulo-interstitial fibrosis correlates with the risk of progression to ESKD.

The glomerular capillary wall is susceptible to immune-mediated injury, most often from humoral immunity (meaning that antibodies bind an antigen and elicit an immune response).[3,4] The assumption is that the glomerulus is particularly prone to antibody attack because high blood flow and high capillary hydrostatic pressure expose the glomerular filter to more antibody than capillary beds elsewhere in the body. When antibodies attack the glomerulus, they can do so in many ways. Antibodies can be specific to glomerular antigens that are endogenous (proteins from our own body), such as Goodpasture's syndrome, in which auto-antibodies are formed against the alpha-3 subunit of type IV collagen. Antibodies can also arise from exogenous antigens, such viral or bacterial proteins, leading to glomerular disease via several potential mechanisms. First, if antibodies to exogenous antigens cross-react with glomerular proteins (molecular mimicry), then mildly cross-reactive antibodies may reach the threshold for activating an immune response within the glomerulus. Second, circulating viral or bacterial antigens can be deposited on the glomerular filter by filtration pressure, and then attract an inflammatory response to foreign antigen, causing collateral damage to the glomerulus. This mechanism of injury is termed "in-situ immune complex formation" and is the primary pathophysiology underlying post-streptococcal glomerulonephritis. Third, antibody-antigen complexes can form within the circulation and then become passively entrapped in the glomerulus, which can attract an inflammatory response to the glomerulus. This mechanism of injury is termed "circulating immune complex formation" and it is the primary pathophysiology for hepatitis C–mixed-essential cryoglobulinemia. With each of these three mechanisms the severity of the inflammatory injury depends on several factors, the first being the relative rates at which antibody-antigen complexes are formed on the glomerular filter, versus how fast these antibody-antigen complexes are cleared away by podocyte endocytosis and mesangial recirculation of GBM proteins. An additional variable is that not all antibodies cause inflammation in the same manner.[4] In summary, antibodies are a common cause of glomerular disease, but the clinical features vary depending on which layer or cell or specific antigen within the glomerulus is targeted by the antibody, the rate at which antibody-antigen complexes are formed and removed, the type of inflammatory response elicited by a particular antibody-antigen complex, and more.

With respect to cellular immunity, neutrophils are a prominent feature of post-streptococcal glomerulonephritis, ANCA-vasculitis and proliferative lupus nephritis; monocytes and macrophages are components of cellular crescents in cases of rapidly progressive glomerulonephritis; and sensitized T-cells can also be detected in cellular crescents. In each case, however, these cells are not the primary cause of glomerulonephritis; they cause great damage but are responding to a cytokine alarm released by the initial cause. Experimentally, T-cells can attack the glomerulus in the absence of antibody deposition (similar to cellular-mediated rejection of a kidney transplant),[5] but it is very rare to see T-cell induced glomerular inflammation without antibody deposition in native kidneys (as opposed to transplant kidneys). The last circulating cell to mention is the diminutive platelet, which can cause glomerular disease in the absence of antibodies (such as with HUS/TTP) or in conjunction with antibodies (such as with lupus anti-coagulant). In combination, humoral and cellular immunity can activate an immune response within the glomerulus, and in conjunction with a host of molecular pathways including reactive oxygen species, proteinases, eicosanoids, and procoagulants, can alter the permeability, blood flow, and function of the glomeruli.[4] Vascular constriction and occlusion follow and result in the eventual destruction of glomeruli, which means that the entire nephron is lost.

CLINICAL PRESENTATION OF GENERALIZED GLOMERULAR DISEASE

It is easier to appreciate the differences between glomerular diseases by understanding the general symptoms, physical exam signs, and laboratory abnormalities of glomerular diseases in general. The five principal clinical features of glomerular disease are proteinuria, hematuria, hypertension, edema, and loss of kidney function, which are often categorized into one of two broad clinical phenotypes: nephritic syndrome or nephrotic syndrome. Nephritic syndromes are generally caused by inflammatory damage to the glomerulus, and use the suffix "itis," such as glomerulonephritis or renal vasculitis. Nephrotic syndromes are generally caused by noninflammatory damage and use the suffix "pathy" such as membranous glomerulopathy. When we discuss individual glomerular diseases, many of them are purely nephritic (such as anti-GBM nephritis) or nephrotic (such as minimal change disease), but others have an overlap of nephritic-nephrotic features (such as hepatitis C cryoglobulinemia). In addition, some glomerular diseases such as lupus nephritis are not a "single" disease and can present with pure nephritic syndrome in some patients (class III lupus) and pure nephrotic syndrome in other patients (class V lupus nephritis) (see **Table e66-1**). Lastly, in clinical practice, an individual with glomerular disease may have some but not all the characteristics of nephritic or nephrotic syndrome. To meet criteria for nephritic syndrome, a patient should have glomerular hematuria along with proteinuria and hypertension. Similarly, a patient can have nephrotic-range proteinuria (greater than 3.5 g/day), but to meet criteria for the full nephrotic syndrome, one must also have a serum albumin less than 3.5 g/dL (35 g/L) and peripheral edema on physical exam.

CLINICAL PRESENTATION OF GLOMERULAR DISEASE

NEPHRITIC SYNDROME

- Hematuria, with dysmorphic red blood cells and red blood cell casts
- Hypertension, sometimes severe
- Edema, usually mild-moderate
- Proteinuria, usually less than 3.5 g/day
- Loss of kidney function (measured by rising serum creatinine or falling eGFR), sometimes progressing to ESKD in weeks
- Sterile pyuria, with white cell casts

NEPHROTIC SYNDROME

- Edema, which can be massive, with weight gain from fluid retention
- Proteinuria of more than 3.5 g/day
- Serum albumin less than 3.5 g/dL (35 g/L)
- Loss of other serum proteins may cause hypercoagulability or immunodeficiency
- Hyperlipidemia with lipiduria (lipid casts and oval fat bodies)
- Kidney function can be normal or decreased, and if decreasing usually takes many years.

- Some glomerular diseases overlap nephritic and nephrotic features

TABLE e66-1

Classification of Lupus Nephritis Based on World Health Organization Criteria

	Light Microscopy of Biopsy	Immuno-Fluorescence	Electron Microscopy	Typical clinical Symptoms
WHO Class I	Normal	Negative staining	Normal*	Mild proteinuria, ~ 500 mg/day*
WHO Class II “mesangial”	Increased number of mesangial cells +/− matrix. Glomerular loops appear normal	Mesangium stains with multiple antibodies	Electron dense deposits are within the mesangium, and sometimes in contiguous parts of the GBM.	Microscopic hematuria and mild proteinuria, ~ 500 mg/day*
WHO Class III “focal proliferative”	Less than 50% of glomeruli with either: 1. Increased number of glomerular cells (endothelial, mesangial, and infiltrating inflammatory cells). 2. Crescentic lesions in Bowman’s space of parietal cells +/− macrophages, lymphocytes, fibroblasts.	Glomerular loops and the mesangium stain with nearly every antibody for “full house” staining.	Electron dense deposits are within mesangium and subendothelial GBM.	Mild-moderate nephritic syndrome +/− some extra-renal symptoms.
WHO Class IV “diffuse proliferative”	More than 50% of glomeruli with either: 1. Increased number of glomerular cells (endothelial, mesangial, and infiltrating inflammatory cells). 2. Crescentic lesions in Bowman’s space of	Glomerular loops and the mesangium have “full house” staining.	Significant electron dense deposits within mesangium, subendothelial and intra-membranous	Moderate-severe nephritic syndrome + several extra-renal symptoms

	parietal cells +/– macrophages, lymphocytes, fibroblasts.		GBM.	
WHO Class V "membranous"	Class V can appear on its own (rarely) in which case the LM looks like membranous. "Spikes" are seen but might need silver stain or PAS to visualize the spikes. More often, class V appears in combination with class 3 or 4, in which case we say Class 3+5.	If membranous alone, the IF will have "full house" staining, distinguishing it from primary membranous. When seen with class 3+5 or class 4+5, the IF is already profoundly positive.	If membranous alone, deposits will be sub-epithelial. If class 3+5 or 4+5, then all of the mesangial, sub-endothelial and intra-membranous deposits from class 3 or 4 are joined by sub-epithelial GBM deposits from class 5.	Nephrotic syndrome if only class V, but this is rare. Class V is most often seen in combination with class III or class IV on biopsy, and the clinical situation for these patients will also be an overlap: mixed nephrotic-nephritic syndrome.
WHO Class VI "sclerosis"	No evidence of any cellular proliferation in the mesangium, glomerular loops or interstitium. Widespread fibrosis. Essentially, this is scar tissue from years of prior lupus nephritis.	Staining may be a mix of old granular staining with a high amount of background staining.	If there is very little normal kidney under light microscopy, then it is difficult to know "where" the deposits are. EM does not add much.	CKD stage 4/5.
Thrombotic microangiopathy with SLE - Not part of WHO classification	As with other causes of TMA, fibrin thrombi within glomerular capillary loops, leading to glomerular ischemia and GBM wrinkling and collapse of loops. Arterioles may show acute thrombi, chronic recanalization of thrombi, or reactive intimal hyperplasia of vessels. Thrombosis of larger arteries can infarct a wedge of renal cortex.	Thrombi should stain for fibrinogen	Platelets rich in granules may be seen within thrombi. Podocyte foot processes may be effaced, not due to proteinuria, but due to glomerular ischemia/loss of cellular architecture.	In pure form, a rising serum creatinine / falling kidney function, without hematuria or proteinuria. But can also be combined with proliferative lupus nephritis.

WHO, Word Health Organization; GBM, glomerular basement membrane; EM, electron microscopy; CKD, chronic kidney disease; LM, light microscopy; PAS, periodic acid–Schiff stain; SLE, systemic lupus erythematosus; TMA, thrombotic microangiopathy.

Proteinuria

Proteinuria is the most important feature of glomerular disease. In normal urine without glomerular disease, the most common protein (40%-50% of total urine protein) is uromodulin, also called Tamm-Horsfall protein, which renal tubules intentionally excrete into urine, and which forms hyaline casts when it crystalizes. The next most common proteins in normal urine are serum albumin and antibodies, which are lost in urine despite the best efforts of the glomerular filter. Since albumin and antibodies are the predominant proteins in blood, and such a large amount of blood undergoes filtration, the loss of a tiny percentage is not surprising. With respect to serum albumin, normal urine contains 15 to 30 mg/day, or about 20% of the total proteinuria. The remainder of protein in normal urine includes microscopic amounts of 1,000s other serum proteins that are lost through the filter, as well as other proteins that are secreted by tubules at much smaller amounts than uromodulin.

With this in mind the normal amount of protein in a 24-hour urine collection should be between 100 and 200 mg/day. A spot urine protein/creatinine ratio correlates with a 24-hour urine collection and should be 100 to 200 mg protein/gram of urine creatinine. Similarly, since the total amount of albumin per day should be 15 to 30 mg, a spot urine albumin/creatinine ratio should be less than 30 mg/g urine creatinine (3.4 mg/mmol creatinine). The spot urine albumin/creatinine ratio will always be less than the total protein/creatinine ratio, both in normal urine and with glomerular disease. Lastly, a urinalysis test strip primarily detects albumin (but for simplicity is inaccurately labeled as “protein”), so a urine dipstick should normally read “negative” or at most, “trace,” which is 15 mg/dL (150 mg/L) of albumin.

If proteinuria or albuminuria is greater than normal on any of these tests, then the patient might have glomerular disease. Whether the proteinuria is due to glomerular disease or not, the presence of excess proteinuria or albuminuria has prognostic value and is associated with increased all-cause mortality, increased risk of progression to ESKD, and increased fatal and nonfatal cardiovascular events.[6] But first, while proteinuria is the most important feature of glomerular disease, there are actually three basic causes of proteinuria, and a bit of detective work is needed to determine whether the problem is glomerular proteinuria, tubular proteinuria, or overflow proteinuria.

Glomerular Proteinuria

With glomerular proteinuria, excessive serum protein is leaking through the glomerular filter, as described above with the analogy of poking holes in a coffee filter with a pencil. The predominant protein in urine will be serum albumin, not because it leaks through the glomerular filter more easily than other serum proteins, but because it is the major protein in serum. Other notable serum proteins that are lost with glomerular proteinuria include coagulation factors, protein that normally keep material within the serum (like iron-binding transferrin, or vitamin-D binding protein), and serum antibodies. The magnitude of proteinuria with glomerular disease can be normal or only slightly above normal with mild disease and becomes clinically concerning at 500 to 1,000 mg/day. It is termed “sub-nephrotic” if the proteinuria is elevated but less than 3,500 mg/day, “nephrotic range proteinuria” if greater than 3,500 mg/day, and in rare cases can be as high as 20,000 to 30,000 mg/day.

Tubular Proteinuria

With tubular proteinuria, the problem is not excess serum protein leaking through the glomerular filter but incomplete reabsorption of protein by renal tubules. In clinical practice, distinguishing glomerular from tubular proteinuria is sometimes difficult, and some additional detail will help illustrate the difference between the two. Tubular proteinuria arises because the glomerular filter is very good but not perfect. Roughly 3,000 mg of albumin per day gets through the glomerular filter.[7] Since the normal albumin concentration in blood is 4 g/dL, which is 40 g/L, and our glomeruli filter 170 L/day, this translates to 6,800 g of albumin/day, or 6,800,000 mg of albumin/day through the glomerulus. If 3,000 mg/day of albumin is lost through the glomerular filter, the performance of the filter is remarkable, but even 3,000 mg of lost albumin is valuable. Accordingly, of this roughly 3,000 mg that makes it through the glomerular filter, our renal tubules reclaim all but about 15 to 30 mg/day, along with reclamation of other valuable molecules that make it through the filter, including smaller proteins, polypeptides, amino acids, glucose, and more. These details illustrate several points: (1) The final amount of albumin in normal urine (15-30 mg/day) arises from the combined efforts of a very good glomerular filter followed by very good tubular reuptake. (2) In patients who have 500 to 3,000 mg/day of proteinuria, without considering other features, both glomerular and tubular proteinuria should be considered, whereas in patients with more than 3,000 mg/day proteinuria, the cause is almost always glomerular disease. (3) The size of protein can help distinguish whether the proteinuria is caused by glomerular versus tubular disease. For instance, in a hypothetical patient with 2,000 mg proteinuria, if caused by pure glomerular disease, albumin will constitute more than 50% of the protein when separated by size using gel electrophoresis. By contrast, the same 2,000 mg/day in a patient with pure tubular proteinuria will have a lower percentage of albumin and a higher percentage of small and medium-size proteins, because the glomerular filter is still functioning as a size and charge barrier (see **Fig. e66-3** above). (4) Patients with tubular proteinuria should not have microscopic hematuria, because the glomerular filter is still functioning. (5) Unlike glomerular disease, tubular proteinuria is often accompanied by urinary loss of other valuable molecules that are normally reabsorbed by renal tubules, such as excessive glucose in the urine in the absence of diabetes, or excessive phosphate in the urine causing low serum phosphate levels. Classic causes of tubular proteinuria include rare genetic conditions (Wilson’s disease, hereditary fructose intolerance, Dent’s disease), drugs with tubular toxicity (aminoglycosides, tenofovir, cisplatin, ifosfamide), heavy metals (lead and mercury), and a subset of patients with myeloma who have light-chain proximal tubulopathy.

Overflow Proteinuria

The third type of proteinuria is “overflow proteinuria” in which the serum has excessive amounts of a protein other than albumin, and this protein “overflows” the combined safeguards of the glomerular filter and tubular reuptake to end up in the urine. This nonalbumin serum protein is almost always an antibody, either a monoclonal gammopathy (a clone of one antibody, such as from multiple myeloma) or a polyclonal gammopathy (an excess of many thousands of antibodies, due to inflammation from a chronic infection such as viral hepatitis, or due to an autoimmune disease such as rheumatoid arthritis). Like tubular proteinuria, overflow proteinuria is important to distinguish from glomerular disease. If the cause is myeloma, then prompt chemotherapy is needed. If the cause is a polyclonal gammopathy, then additional tests are needed to diagnose the infection or autoimmune condition.

Hematuria

Hematuria is a major feature of nephritic glomerular disease and is also found to a lesser degree in some nephrotic glomerular diseases. To begin with, normal urine should test negative for blood on urinalysis, and under a microscope there should be 0 to 2 red blood cells per high power field (40× objective). If more blood than this is present in urine, then we use the term “gross hematuria” if the color of blood in urine is grossly visible to the naked eye, and we use the term “microscopic hematuria” if blood is visible only by microscope. Gross hematuria actually requires only a tiny amount of blood (about 50 µL/L of urine). A third possibility for blood on a urinalysis is a false positive due to rhabdomyolysis or hemolysis, which results in excessive myoglobin or hemoglobin in the urine, and it is these heme-pigments that are detected as “blood” by the chemistry of urinalysis test strips. In these cases, despite a positive test on urinalysis, the number of red blood cells on urine microscopy will be normal.

Hematuria, just like proteinuria, can be caused by both glomerular disease and non-glomerular disease, and the latter is actually more common. Non-glomerular hematuria arises most often when blood leaks from any capillary into the urine collecting system at a spot after the glomerular filter, which could be within renal tubules, collecting ducts, renal pelvis, ureters, bladder, or urethra. Accordingly, the common causes of non-glomerular hematuria are renal cancer, bladder cancer, kidney stones, trauma, or a urine infection causing enough inflammation that the bladder lining becomes friable. In addition, hematuria is sometimes difficult to distinguish from uterine bleeding with atypical menstrual flow, or in post-menopausal women. Lastly, non-glomerular hematuria can arise from rare cases of endometriosis within the ureters, microlithiasis in children without overt stones, or “benign hematuria” due to a non-kidney severe illness, in which case the hematuria should resolve on urinalysis when rechecked 4 to 6 weeks later.

In contrast, glomerular hematuria arises when red blood cells are pushed through the GBM. Under careful microscopic examination of urine, two features can reliably distinguish glomerular from nonglomerular hematuria. Red cells in urine due to a kidney stone, for example, will retain their normal shape as biconcave disks, or they will shrink or swell uniformly if the osmolality of urine is quite different from blood. Conversely, red cells in urine due to glomerular disease often appear “dysmorphic” meaning that the shape of the plasma membrane was disturbed as a consequence of being squeezed through the glomerular filter.[8] Dysmorphic red cells in urine are also termed “acanthocytes” (but their shape is NOT the same as acanthocytes on a peripheral blood smear) or more intuitively they are called “Mickey mouse cells” because the large blebs of red cell membrane resemble giant ears. The second finding on microscopy that distinguishes glomerular from nonglomerular hematuria is red blood cell casts. Red cell casts are highly specific for glomerular hematuria because the cells within any cellular cast must have been present within the early distal nephron when casts are formed. To elaborate, the shell of every cast is formed by uromodulin, which is intentionally secreted into the lumen of the nephron by renal tubule cells in the loop of Henle and ascending limb. As urine filtrate continues to flow into the distal convoluted tubule and collecting tubules, becoming more concentrated and acidic, the uromodulin precipitates into a more organized, lower-energy state, in a manner similar to how some proteins can organize into crystals, but in this case the preferred organization is to form a tube. If there are no cells within the distal nephron when uromodulin precipitates, then a hyaline cast is formed (which is why hyaline casts are a normal finding in urine). If there are any cells within the distal nephron when uromodulin precipitates into casts, then these cells become entrapped into the cast matrix and form a cellular cast. Hematuria from a kidney stone or bladder cancer cannot force red cells within the cast; the hematuria must be present much higher up within the distal nephron, and hematuria at this location is overwhelmingly due to glomerular disease.

Hypertension

Hypertension is common among patients with glomerular diseases, as a result of increased renal sodium retention, and also increased release of vasoconstrictors within the kidney or systemically. Increased sodium retention causes hypertension due to plasma volume expansion, which is almost always present even if peripheral edema is clinically subtle. Increased vasoconstrictors include those released within the kidney, and also those released by vascular endothelium in patients with glomerular disease that is part of a systemic vasculitis. Specifically, both nephritic syndrome and nephrotic syndrome (especially the former) have increased renin activity, which leads to increased angiotensin II formation, a potent vasoconstrictor within both the systemic vessels and within glomerular efferent arterioles. Glomerular disease is also associated with variable increases in sympathetic activity and release of endothelin, which raises blood pressure. The first choice of medications to treat hypertension in glomerular disease is antagonists of the renin-angiotensin system, such as angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs), as described in detail below.

Edema

Edema is common among patients with moderate or severe glomerular disease. A differential of peripheral edema includes: acute or chronic congestive heart failure (which can be systolic or diastolic dysfunction, valvular disease, pulmonary hypertension, or right sided heart failure), decreased sodium excretion due to loss of kidney function (AKI or CKD, which leads to excess sodium balance and expansion of blood volume), lymphatic disease (usually surgical or traumatic damage, very rarely filariasis), or diseases that cause increased capillary leak (usually infectious or inflammatory disorders, very rarely congenital disorders). Edema follows gravity, with greatest severity in the lower legs after standing upright, followed by redistribution around the body after lying down with elevated legs. But some people clearly put more of their edema into ascites than their legs, and other patients are prone to pulmonary edema without legs or ascitic edema.

One explanation for edema in glomerular disease is excess sodium retention, similar to patients with AKI/CKD, but the sodium retention can occur even if kidney function is normal. Historically, there have been two competing hypotheses to explain the cause of edema in patients with nephrotic syndrome. The "overfill hypothesis" of edema contends that the ECF compartments are "overfilled" with salt water due to retention of sodium.[9] Conversely, the "underfill hypothesis" is based on the idea that, according to Starling's law, hydrostatic pressure pushes fluid from pre-capillary arterioles into the extra-cellular space, while oncotic pressure draws fluid back from the extra-cellular space into the post-capillary venules. In short, the idea is that low serum albumin causes edema. It should be noted that a single explanation of edema does not fit all patients and clinical situations.

The third explanation for edema in nephrotic syndrome is leaky capillary membranes. This mechanism did not make it into the main debate of "underfill and overfill" historically, but nephrotic syndrome patients have demonstrated significantly higher capillary leak compared to normal patients.[10] The idea is that, similar to patients with septic shock who develop pulmonary and peripheral edema, the tight junctions between cells become "less tight" within the vasculature in patients with nephrotic syndrome. Research on the mechanisms of capillary leak with glomerular disease is ongoing.

Loss of Kidney Function

Loss of kidney function with glomerular disease is variable, and when it occurs, can manifest as either acute or chronic kidney disease. The most severe examples are patients with rapidly progressive glomerulonephritis (RPGN), which is defined as the nephritic syndrome with loss of 50% or more kidney function (or a doubling of serum creatinine) within 6 weeks. Patients with suspected RPGN should be admitted to the hospital, because every day without treatment can translate into irreversible loss of kidney function. The possible causes of RPGN are discussed at the end of this chapter.

More often, glomerular disease progresses chronically, over months to years. This is the case for hereditary glomerulonephritis from Alport's syndrome, primary membranous glomerulopathy that is refractory to treatment, or severe IgA nephropathy, all of which can progress to ESKD over a few decades. In many cases, progressive CKD occurs even if the cause of glomerular injury has resolved. One reason for this is that, similar to neurons after a stroke, podocytes that die due to glomerular disease cannot be regrown. Neighboring podocytes attempt to stretch over the surface of the glomerulus to compensate, but there is a "point of no return" of approximately 70% podocyte loss within a single glomerulus after which the glomerulus will inevitably die due to glomerulosclerosis.[11] Second, if inflammation or acute kidney injury is severe enough to activate the molecular pathways that cause fibrosis of glomeruli and the tubulo-interstitium, these pathways take time to reverse.[12] Lastly, even in the best case scenario in which kidney injury is halted prior to the "point of no return," full kidney function will not be restored. The healthy kidney tissue that remains can undergo hypertrophy and hyperfiltration, but similar to scar tissue elsewhere in the body, fibrosis is nearly impossible to repair. The percentage of tubulo-interstitial fibrosis is one of the most predictive findings from a kidney biopsy for chronic kidney disease.

Hyperlipidemia

In patients with the full nephrotic syndrome, serum cholesterol and triglycerides can be severely elevated, but can fully normalize if treatment for nephrotic syndrome results in remission. Hyperlipidemia arises because increased liver synthesis of albumin inadvertently also increases liver synthesis lipoproteins, and at the same time, proteinuria results in loss of the serum protein lipoprotein lipase, which leads to decreased conversion of triglycerides into free fatty acids.[13]

Lipiduria

Fatty casts and oval fat bodies are frequently seen in the urine of patients with the nephrotic syndrome. Fatty casts resemble red cell casts (circles with no nucleus) but the circles are lipid droplets of various sizes instead of the uniform size seen with red cells. Under polarized light, the lipid droplets in fatty casts form an X or a “Maltese Cross.”

Increased Risk of Deep Vein Thrombosis and Pulmonary Embolism

Nephrotic syndrome predisposes to clotting disorders. Blood is in constant balance, poised to form a clot in cooperation with platelets if bleeding arises, but also to prevent blood from clotting inappropriately, even if blood flow is sluggish. The liver synthesizes serum proteins on both sides of this see-saw, including anti-thrombin-III, protein C and protein S to prevent clotting, and to promote clotting, fibrinogen along with clotting factors II, V, VII, IX, X, XI, and XII. In patients with low serum albumin due to the nephrotic syndrome, liver synthesis is stimulated to make more serum albumin, and in the process the liver synthesizes other proteins, including those that promote and inhibit coagulation. At the same time, anti-thrombin III is small enough to be lost at high amounts in the urine when proteinuria is significant. The end result is increased risk of clotting, particular renal vein thrombosis (the renal veins are directly after anti-thrombin-III is lost from glomerular filtration into urine), as well as increased risk of deep vein thrombosis and pulmonary embolism.

Increased Risk for Infection

In addition to loss of serum albumin, nephrotic syndrome patients lose antibodies and complement proteins. Children with nephrotic syndrome are at particular risk for peritonitis and pneumococcus. Some patients with severe nephrotic syndrome receive infusion of antibodies (intravenous immune globulin) until they begin to enter clinical remission.

Sterile Pyuria, with White Cell Casts

In many causes of moderate or severe nephritic syndrome, white cells are often seen in the urine. Like other features of glomerular disease, white cells on urine microscopy are not specific for glomerular disease, and can also be seen with colonization from a poor quality clean catch (in which case squamous epithelia will also be present), or with lower urinary tract infections including cystitis. But if white cell casts are seen, then we know from the mechanism of cast formation that these white cells must have been within the distal nephron, so there are only three likely causes: an inflammatory glomerulonephritis, such as lupus nephritis, a pyelonephritis (which has very different clinical symptoms of flank pain, nausea, fever, and low blood pressure), or a tubulo-interstitial nephritis such as allergic interstitial nephritis or sarcoidosis (which should not have glomerular hematuria). In short, pyuria and white cell casts due to glomerular disease should be distinguishable from other causes by additional symptoms and urine findings.

TREATMENT OF GENERALIZED GLOMERULAR DISEASES

Kidney Disease: Improving Global Outcomes (KDIGO) is a global nonprofit foundation dedicated to improving the care and outcomes of kidney disease patients worldwide, and has promoted coordination, collaboration, and integration of initiatives to develop and implement clinical practice guidelines for many kidney diseases. The KDIGO clinical practice guidelines for diagnosing and treating glomerular disease were published in 2012, and updated guidelines from 2020 are available.[14,15]

Treatment of glomerular disease can be broken down into three approaches: (1) treatments aimed at a specific diagnosis, often in the form chemotherapy or immunosuppression that aims to block immune-mediated glomerular disease. Some immunosuppressants are specific to one aspect of the immune system. Other immunosuppressants are very nonspecific and are chosen either because the molecular mechanism of a glomerular disease is not known, or because a glomerular disease dysregulates multiple aspects of immunity at the same time; (2) non-pharmacologic therapies that are generally applicable to all forms of glomerular disease, including various dietary recommendations; (3) pharmacologic therapies that are generally applicable to all forms of glomerular disease. In clinical practice, we refer to the combination of (2) and (3) as "conservative therapy" for glomerular disease.

Chemotherapy or Immunosuppression for Immune-Mediated Glomerular Disease

In this section, we will not describe dose or duration of these therapies, which vary between some glomerular diseases, and which vary between pediatric and adult populations. A modest amount of detail on medication dosing is included later in this chapter when individual glomerular diseases are described, but complete dosing details are beyond the scope of this chapter. Instead, the specific aim of the section below is to introduce the general mechanisms, risks, and benefits of chemotherapy and immunosuppression for patients with glomerular disease. Very often, immunosuppression of glomerular disease involves the use of 2 or 3 of the following medications, either at the same time, or sequentially. For non-inflammatory glomerular diseases, especially those with no known mechanism, it is possible that the benefit of these "immunosuppressant" medications may have nothing to do with the immune system, and may instead be helping by direct signaling to podocytes.[16] The overall risks and benefits of immunosuppression are generally straightforward: the benefit of immunosuppression is to hopefully stop immune-mediated injury, including loss of kidney function and death; the risk of immunosuppression is a predisposition to infection and cancer, and in patients receiving immunosuppression for glomerular disease, infections are the major cause of death. In summary, a delicate balance of immunosuppression is required: too little, and the glomerular disease remains active; too much, and the risk of infection and cancer becomes excessive.

Corticosteroids

Corticosteroids have a rapid anti-inflammatory effect in patients with glomerular disease by inhibiting the release of IL-1 and tumor necrosis factor by activated macrophages and inhibiting the release of interleukin-2 by activated T cells. In turn, production of many other inflammatory mediators is reduced, including prostaglandins, leukotrienes, platelet-activating factors, migration-inhibiting factor, and gamma-interferon. In addition to anti-inflammatory effects, corticosteroids also act through steroid-hormone binding receptors to alter transcription of multiple genes, which includes increasing podocyte expression of Nephrin (a key protein of the podocyte intercellular junction). Chronic steroid therapy can result in problematic side effects such as slowing bone growth in children, insomnia, avascular necrosis of long bones, acne, polyphagia, fluid retention, and mood disorders including mania and aggression. For patients on steroids for more than 10 to 14 days, the adrenal glands may stop making endogenous steroid, resulting in a state of secondary adrenal insufficiency if the corticosteroid dose is suddenly decreased below 5 to 10 mg/day. When stopping corticosteroid therapy, the dose should be lowered to 5 to 10 mg/day and then tapered gradually, monitoring for symptoms, while the adrenal glands restart endogenous steroid biosynthesis. The symptoms of abruptly stopping corticosteroids are those of adrenal insufficiency, and range from nausea/lack of appetite and weakness to hypotension, to full circulatory shock.

Cytotoxic Agents

Cytotoxic agents such as cyclophosphamide and chlorambucil create DNA-crosslinks, which prevent mitosis of dividing white cells (lymphocytes, monocytes, and neutrophils), and also induce apoptosis of white cells. Modest depletion of the number and activity of white cells is the goal of therapy for multiple inflammatory glomerular diseases. Cytotoxic therapy is also used with good response in several noninflammatory glomerular diseases, but usually as a second- or third-line therapy. To avoid excessive white cell depletion (leukopenia and neutropenia), which increases the risk of acquiring infections, complete blood counts are monitored weekly, and then monthly if the dose remains stable. Additional side effects of cytotoxic agents include sterility, hemorrhagic cystitis, alopecia, and the potential for lymphoma with long-term treatment.

Azathioprine

Azathioprine is a purine analog with multiple effects (the main mechanism of effect is uncertain) including misincorporation during DNA replication, which prevents mitosis of replicating immune cells, and suppression of purine synthesis, which prevents RNA synthesis in immune cells. Side effects include nausea and vomiting, leukopenia, megaloblastic anemia, and with long-term therapy, increased risk of nonmelanoma skin cancers.

Calcineurin Inhibitors

Cyclosporine and tacrolimus are calcineurin inhibitors, used to suppress the immune system in patients who receive organ transplant, and who suffer from various autoimmune diseases. Calcineurin inhibitors prevent T-cell activation and suppress IL-2 release. In addition, calcineurin inhibitors stabilize the cytoskeleton of podocytes, and for noninflammatory diseases such as FSGS this is a possible alternative mechanism of action (we do not know which mechanism is most important). Calcineurin inhibitor side effects include hypertension, hyperuricemia with risk of gout, hyperglycemia with risk of diabetes, neurotoxicity with risk of tremor, hyperkalemia, hypomagnesemia, and with long-term use, the risk of kidney toxicity. Cyclosporine has the additional side effects of gingival hyperplasia and hypertrichosis. Both drugs are metabolized by cytochrome P450 3A4/5 and have multiple drug-drug interactions that can affect therapeutic drug concentrations.

Mycophenolate

Mycophenolate is an analog of inosine and inhibits guanosine synthesis, especially the isoform that is present in activated B and T cells, resulting in suppression of lymphocyte proliferation (lymphopenia), and suppression of antibody production. Mycophenolic acid is the active drug, which can be administered as Mycophenolate mofetil (MMF) or sodium mycophenolate (SMP). For most glomerular diseases, MMF is administered at 1,500 to 3,000 mg/day in two divided doses, or SMP at 1,440 mg/day.[15] Overall, mycophenolate is well tolerated. Side effects that require dose reduction include leukopenia, nausea, diarrhea, or an excessive number of infections.

Rituximab

Rituximab is a monoclonal antibody against CD-20, which is present on pre-B cells and mature B cells but not on plasma cells. Rituximab binding to cells causes complement-mediated cytotoxicity and antibody-mediated cytotoxicity. CD-20 is also expressed on podocytes, so an alternative mechanism of action for some glomerular diseases is direct signaling to podocytes. Side effects of rituximab are generally mild and include infusion reactions (managed by premedication with anti-histamine and acetaminophen, with or without steroids) and increased risk of infection or reactivation of chronic infections (like hepatitis B or varicella viruses) due to B-cell depletion.

Plasmapheresis

Plasmapheresis or plasma exchange therapy can remove serum proteins that include auto-antibodies attacking the glomerulus, and then replace what is removed from the blood with either albumin or fresh-frozen plasma. Plasmapheresis also removes additional inflammatory mediators and has an immunosuppressive effect that is greater than simply the reduction of antibody levels. Plasmapheresis is usually reserved for only the most severe glomerular diseases. The best evidence for a clinical benefit with plasmapheresis is in patients with anti-GBM nephritis, which is discussed at the end of this chapter.[17] Plasmapheresis is sometimes used in patients with pulmonary-renal syndrome due to ANCA-vasculitis or mixed-essential cryoglobulinemia, but the clinical benefit in these patients is being questioned based on negative results from the randomized controlled Pexivas trial,[18] as well as negative results from a large retrospective review.[19]

Nonpharmacologic Therapies

Nonpharmacologic therapies for all glomerular diseases include sodium restriction to less than 100 mEq/day, which is important for the control of hypertension, edema, and proteinuria; low-fat diet for patients with nephrotic syndrome who have secondary hyperlipidemia; and possible dietary protein restriction. A common recommendation in CKD patients is to restriction protein intake to about 0.8 g/kg body weight/day. Protein restriction in glomerular disease is controversial. Protein restriction is not recommended for patients with the full nephrotic syndrome because intake of protein will be easily outpaced by urinary loss of protein, resulting in protein-calorie malnutrition. A simplified recommendation is for patients with glomerular disease to avoid fad diets with excessive protein intake. Moreover, in patients with severe edema, which can cause pain, skin blistering, skin ulceration, and acute stasis dermatitis, edema usually follows gravity. Edema can be treated without medications by elevating legs, and by using compression stockings each morning, placed when legs are least swollen. Smoking cessation is recommended for all patients with chronic kidney disease including glomerular disease, to decrease the risk of cardiovascular events.[20]

Pharmacologic Therapies

Pharmacologic therapies that are commonly utilized in the treatment of glomerular disease include diuretics, antihypertensive medications, lipid lowering drugs, and others as described below.

Diuretics

Diuretics act to remove excess total body sodium. Sodium retention is common among patients with glomerular disease, leading to hypertension, edema, or both. Loop diuretics block the largest percentage of filtered sodium from being reabsorbed (~ 25%-30%), which is why they are the most effective class of diuretics. In patients with glomerular disease, increased "resistance" to loop diuretics is common and is due to several causes including:

- Decreased delivery of diuretic to the site of action in the lumen of the thick ascending limb of the loop of Henle. Loop diuretics are protein bound and only minimal amounts undergo glomerular filtration. Loop diuretics reach their site of action after transport through channels into proximal tubules and then from tubules into the lumen. Once inside the tubular lumen, the loop diuretic flows through the loop of Henle and then binds to the sodium-potassium-chloride cotransporter in the thick ascending limb from the luminal side of the channel. While loop diuretics are not filtered, the process of tubular uptake and tubular secretion of diuretic requires kidney "function" and correlates with glomerular filtration rate (GFR). As GFR decreases, higher doses of loop diuretic are required to achieve concentrations within the tubular lumen necessary for inhibiting sodium reabsorption.

- Binding of loop diuretics to albumin within the filtrate. Proteinuria results in excess albumin in the filtrate, which binds to diuretic within the lumen and decreases the amount of free (ie, nonprotein bound) diuretic available to bind the sodium-potassium-chloride cotransporter.

- The "braking" phenomenon, which refers to the gradual decrease (like applying the brakes of a car) of the clinical response to loop diuretics after daily use for weeks to months.[21] When loop diuretics successfully block sodium reuptake in the thick ascending limb, an increased amount of sodium is presented to the next segment of the nephron, which is the thin limb and distal convoluted tubule, containing the thiazide-sensitive sodium-chloride cotransporter. When loop diuretics are used chronically, the increased sodium load to the distal convolute tubule leads to adaptation, including hypertrophy (the cells become visibly larger), and greater density of sodium-chloride cotransporters per cell. In short, loop diuretic resistance develops over time because other parts of the nephron fight the diuretic effect. In these patients, the addition of a thiazide diuretic to block the overactive sodium-chloride cotransporters can overcome the resistance.[22]

- Reduced drug absorption due to bowel wall edema. This is a common explanation in clinical practice for loop diuretic resistance, but the effect is more likely from decreased blood flow during decompensated CHF, rather than the edema per se.[23] Another possibility is that gastrointestinal absorption may be decreased, but this effect should be confined to furosemide, which has a lower and more variable oral bioavailability than torsemide or bumetanide.[24]

Whether from changes in oral bioavailability or not, maximal diuretic effect depends on peak serum concentration of diuretic, which can be achieved by intravenous administration, either as a bolus or as a continuous infusion.[25] For patients with morbid edema, albumin (25%) infusions have been attempted to expand plasma volume and increase diuretic delivery to the renal tubules, but the effectiveness of combined albumin-diuretic therapy is minimal or negative.[26–28] Regardless of what dose or combination of diuretics is required, the goal of diuretic therapy in patients with glomerular disease and sodium overload is a slow and steady diuresis of 0.5 to 1.5 kg of weight daily until all excess salt water has been removed.

Antihypertensive Medications

According to Joint National Committee (JNC) 8 guidelines, the target blood pressure for patients with CKD is less than 130/80 mm Hg.[29] In patients with glomerular disease, many experts advocate gently pushing the blood pressure lower if tolerated, especially in patients with nephrotic range proteinuria, but this is not based on gold-standard data. The NIH-sponsored SPRINT trial showed that targeting a systolic blood pressure of less than 120 mm Hg, as compared with less than 140 mm Hg, resulted in lower rates of fatal and nonfatal major cardiovascular events and death from any cause.[30] An analysis of patients in the SPRINT trial with nondiabetic CKD found that the more intensive blood pressure goal (systolic blood pressure <120 mm Hg) was associated with lower rates of cardiovascular outcomes, renal outcomes, and death compared to the <140 mm Hg group.[31] There were some increased adverse events from blood pressures that were "too low" in the SPRINT trial, but it is anticipated that the next JNC guidelines will include lower blood pressure targets for at least a subset of patients with CKD.

Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) are the first choice for all patients with glomerular disease who have hypertension and proteinuria. These medications delay the long-term loss of kidney function for patients with diabetic kidney disease, as well as some nondiabetic (primarily glomerulonephritis) kidney diseases. These medications, as well as antagonists to the mineralocorticoid receptor (spironolactone and eplerenone) also decrease proteinuria, which is independently associated with increased risk of kidney disease progression and major adverse cardiac events.[32] By indirectly or directly blocking the angiotensin receptor, ACEIs and ARBs reduce intraglomerular pressure. Additional mechanisms of action may include direct inhibition of RAAS signaling, and inhibition of pro-fibrotic pathways within the kidney. These beneficial effects on proteinuria are beyond what can be attributed by the drug's antihypertensive effects.

Combined use of ACEIs and ARBs can maximize blockade of the renin–angiotensin system by counteracting angiotensin II produced by non-ACE pathways,[33] which reduces proteinuria and slows the progression of CKD more than either treatment alone.[34] However, current recommendation are to avoid combination RAAS blockade due to increased adverse effects of hyperkalemia, acute kidney injury, and nonfatal stroke. Ongoing studies may help define the best balance between benefit and risk for dual or triple blockade of the RAAS system.[35]

If maximal doses of ACEIs or ARBs do not control blood pressure to goal, then a second medication must be added, which for glomerular disease is either a diuretic or a non-dihydropyridine calcium channel blocker. Diuretics are a better choice if both edema and hypertension are present, while non-dihydropyridine calcium channel blockers such as diltiazem or verapamil have modest anti-proteinuric effects and are a better choice if a patient needs to avoid hypokalemia from diuretics, or would benefit from reducing the heart rate by calcium channel blockade. Verapamil and diltiazem also serve as alternative first-line therapy in patients with angioedema or severe intolerance to ACEIs or ARBs.[36] Dihydropyridine calcium channel blockers such as amlodipine or extended-release nifedipine, on the other hand, are excellent at reducing systemic blood pressure but tend to increase intra-glomerular blood pressure, and if possible are avoided in patients with glomerular disease. If hypertension in glomerular disease is severe and requires three medications to reach goal, then like other forms of hypertension, one of the three medications should always be a diuretic (see Chapter 30).[29]

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) can cause CKD due to analgesic nephropathy, or AKI due to inhibition of prostaglandin-mediated compensation of afferent glomerular arteriole flow, or in rare instances allergic interstitial nephritis with significant proteinuria due to minimal change nephropathy (see Chapter 65). Nevertheless, it is formally true that NSAIDS have an anti-proteinuric effect. Indomethacin has a similar efficacy to ACEIs, and combined treatment with an ACEI results in additional proteinuria reduction.[37] However, the risks of AKI and CKD from NSAIDS outweigh the potential benefits.

Statins

Hyperlipidemia in patients with nephrotic syndrome can be severe, and there is a long-term association of nephrotic syndrome with atherosclerotic cardiovascular disease.[38] HMG-CoA reductase inhibitors, also known as "statins," such as pravastatin, simvastatin, atorvastatin, and rosuvastatin, are considered the treatment of choice.[39] They reduce total plasma cholesterol concentration, LDL cholesterol, and total plasma triglyceride concentrations (see Chapter 32). Aside from the lipid-lowering effects, statins can reduce cardiovascular risk independent of serum lipid concentrations. However, in contrast to the very clear clinical data showing benefit of statins in people with several cardiovascular conditions, currently there is not clinical data showing that statins prevent cardiovascular events in patients with glomerular disease.

Alirocumab and Evolocumab

Alirocumab and evolocumab are inhibitors of proprotein convertase subtilisin/kexin type 9 serine protease (PCSK9). Inhibition of PCSK9 by these recently developed medications leads to increased recirculation of the LDL receptor to the hepatocyte surface and accelerated clearance of circulating LDL (see Chapter 32). These medications may be especially useful in treating hypercholesterolemia in patients who have nephrotic syndrome and those on peritoneal dialysis, since they tend to have high PCSK9 concentrations.[40] However, the benefit of these agents for kidney function and cardiovascular outcomes need to be demonstrated in large clinical trials.

Anticoagulation

Thromboembolic events including renal vein thrombosis, deep vein thrombosis, and pulmonary embolism are complications of severe nephrotic syndrome. Patients with documented thromboembolic events should be anticoagulated. Whether or not to start prophylactic anticoagulation in patients with the nephrotic syndrome is controversial, and the decision process balances the severity of nephrotic syndrome, additional risk factors for thrombosis such as immobility, risk for hypovolemia, timing of possibly surgery, fall risk, patient profession, and history of prior bleeding events.[41,42]

SGLT-2 Inhibitors

Sodium-glucose co-transporter 2 (SGLT2) inhibitors block one of two classes of glucose re-uptake channels in the proximal tubule, leading to excess amounts of glucose in the urine. These new medications were originally intended to lower blood glucose in diabetic patients. However, they were also shown to reduce cardiovascular events among diabetics (the first medication to do so), and to slow the progression of kidney disease (see Chapter 94). In the kidneys, the SGLT-2 inhibitors appear to re-set the process of tubo-glomerular feedback and, similar to RAAS blockade, this decreases intra-glomerular pressure, decreases proteinuria, and prolongs long-term kidney function. The SGLT-2 inhibitors are a key, new medication for patients with diabetic nephropathy. The drugs also show a clinical benefit in patients without overt diabetic nephropathy, and it is possible that these medications may benefit patients with glomerular diseases other than diabetes.[43]

EVALUATION, DIAGNOSIS, AND ASSESSMENT OF THERAPEUTIC OUTCOMES

Evaluation and Diagnosis

If a patient is suspected of having glomerular disease based on hematuria, then microscopic examination of the urine can help distinguish non-glomerular hematuria from glomerular disease. If the suspicion of glomerular disease is based on proteinuria, then quantification of the amount and type of protein can distinguish glomerular proteinuria from tubular proteinuria and overflow proteinuria. The presence of hypertension and testing kidney function based on serum creatinine can determine the extent of kidney damage and stratify the initial approach to therapy. In the early stages of glomerular disease, serum creatinine can be deceptively normal because the remainder of the kidney will attempt to compensate by hyperfiltration and by increased tubular secretion of creatinine from remaining nephrons.

Patients with suspected glomerular disease should undergo an extensive medical history to identify potential systemic causes (see **Table e66-2**). Medication, environmental, and occupational histories may also help identify exposure to potentially nephrotoxic agents. A comprehensive physical examination and laboratory evaluation may reveal the presence of systemic diseases that may contribute to the development of glomerular disease. In addition, the patient's age, gender, and ethnic background may be helpful in pinpointing the specific type of glomerular disease. For example, lupus nephritis is more common in young women, whereas ANCA-associated vasculitis is dramatically higher in older patients.

TABLE e66-2

Evaluation of Patients Suspected of Having Glomerular Disease

Medical history

To identify symptoms of medical conditions that may cause glomerular disease

- Diabetes mellitus
- Amyloidosis
- Systemic lupus erythematosus
- Other familial conditions associated with kidney disease

To identify symptoms suggestive of nephrotic syndrome

- Reduced appetite
- Fatigue
- Weight gain
- Edema

Medication, environmental, and occupational histories

To identify possible exposure to potentially nephrotoxic drugs, toxins, or chemicals

Physical examination

To identify signs and symptoms associated with systemic diseases

- Hypertension

- Rash
- Arthritis
- Retinopathy
- Neuropathy
- Lymphadenopathy
- Hepatomegaly
- Malignancy

Laboratory evaluation

Urinalysis

- To determine nephrotic nature of glomerular disease
- Proteinuria, >3.5 g/day/1.73 m^2
- Lipiduria
- To determine nephritic nature of glomerular disease
- Hematuria
- Pyuria
- Cellular, granular casts

Glomerular filtration rate

- To determine extent of glomerular damage

Other tests

- To identify type and etiology of glomerular disease
- Serum complement concentration
- Antinuclear and anti-DNA antibodies
- Antistreptolysin antibodies
- Circulating antiglomerular basement membrane antibodies
- Cryoglobulins

Percutaneous kidney biopsy

- To provide definitive diagnosis of glomerular disease

In most cases of severe glomerular disease for which immunuosuppressive therapy is being considered, a kidney biopsy is needed to provide a definitive diagnosis. The main risk of kidney disease is bleeding, due to the fact that the kidneys receive ~ 20% of cardiac output. Safety measures for kidney biopsy include controlling the blood pressure to less than 150/90 before and after biopsy, stopping all reversible and irreversible platelet inhibitors (NSAIDs, aspirin, clopidogrel) and anticoagulants, ensuring stable and adequate hemoglobin and platelet counts beforehand (preferably a hemoglobin >10 g/dL [100 g/L; 6.21 mmol/L] and platelet count >100,000/µL [100 x 10^9/L]), the ability for the patient to position correctly and calmly (usually lying supine, and kidneys are accessed percutaneously through the mid-back), and the ability to provide informed consent.

Assessment of Therapeutic Outcomes

After a specific diagnosis of glomerular disease is made, a treatment plan with monitoring must be instituted. Some treatments require physical exam and lab monitoring for potential toxicity, and to decide whether the glomerular disease is responding to therapy (see **Table e66-3**). Serum creatinine concentration as well as creatinine clearance should be evaluated prior to and during treatment. For patients suspected of having significant proteinuria, the gold standard measurement is by 24-hour urine collection. Proteinuria may also be estimated from the ratio of urine total protein to urine creatinine random urine collection, and overall there is good correlation of the random protein/creatinine ratio with 24-hour urine proteinuria.[44] Electrolytes are monitored for changes due either to the glomerular disease, or due to medications such as diuretics or RAAS inhibition. Home blood pressure monitoring should be performed regularly to assess the need for and/or the adequacy of antihypertensive therapy. Edema and fluid overload should be assessed regularly to gauge the need for diuretic initiation or dosage modification. For patients with nephrotic syndrome, serum lipid concentrations should be monitored at least quarterly. For patients with hematuria, urinalysis and a complete blood count should be obtained. The clinician should also be aware of the patient's appetite and energy level because these are indicators of a patient's overall well-being. After initial diagnosis, a repeat kidney biopsy may be needed in some cases to assess response to treatment and disease progression, to determine future treatment strategy, or to confirm the initial diagnosis. Patients receiving cytotoxic drug treatment should be evaluated to gauge their response and identify the presence of drug-related toxicities, with the frequency of monitoring varying from weekly to monthly to quarterly, depending on which drug is utilized.

TABLE e66-3

Monitoring Parameters to Assess Response to Glomerular Disease Treatment

- Kidney function
    - Serum creatinine concentration
    - 24-hour urine collection for creatinine clearance determination
    - 24-hour urine collection for urinary protein excretion
    - Urine protein-to-creatinine ratio
- Clinical signs and symptoms
    - Nephrotic syndrome
        - Proteinuria
        - Serum lipid concentrations
        - Edema
    - Nephritic presentations
        - Hematuria
        - Urinalysis
        - Complete blood count
    - Blood pressure
    - General well-being: appetite, energy level
- Kidney biopsy to assess disease progression and response to therapy
- Assessment of drug therapy adverse reactions and toxicities

The frequency of monitoring is dependent on the specific glomerulopathy and severity of the disease.

NONINFLAMMATORY GLOMERULAR DISEASES

Noninflammatory glomerular diseases often cause the nephrotic syndrome. The main causes of noninflammatory glomerular disease are minimal change disease, focal segmental glomerulosclerosis (FSGS), membranous nephropathy (MN), and dysproteinemias including myeloma, light-chain deposition disease, and amyloidosis. While membranoproliferative glomerulonephritis (MPGN) often causes a mixed nephrotic-nephritic syndrome, it is discussed with inflammatory glomerulonephritis. Diabetic nephropathy is characterized by proteinuria that sometimes rises to nephrotic-level (see Chapter 94).

Minimal-Change Disease

Minimal-change nephropathy (also termed "nil disease" or "lipoid nephrosis") is the most common cause of nephrotic syndrome in children, accounting for 85% to 90% of nephrotic syndrome in children between 1 and 4 years of age. The percentage drops to less than 50% after age 10 and it accounts for less than 20% of all primary nephrotic syndrome in adults. Minimal change is usually primary (idiopathic) for which a molecular mechanism still has not been identified. A minority of patients have "secondary" minimal change, meaning that the disease arose secondary (because of) something else, such as a medication side effect or an infection. Causes of secondary minimal change disease include: NSAIDs (usually seen in combination with NSAID-induced allergic interstitial nephritis), lithium, HIV infection, Epstein-Barr viral infection, or occasionally T-cell lymphomas/leukemias.

Clinical Presentation

Minimal change disease usually presents with sudden onset edema and weight gain. Blood pressure is usually normal, as is kidney function, but patients have the full nephrotic syndrome, including nephrotic range proteinuria, hypoalbuminemia, edema, and hyperlipidemia. Under microscopy the urine sediment is negative for hematuria and cellular casts but can have oval fat bodies and fatty casts due to lipiduria. There are no serological tests, and the diagnosis can only be made on kidney biopsy. By light microscopy and immunofluorescence, the glomeruli appear normal, and electron microscopy is required to find an abnormality, hence the term "minimal change." Under electron microscopy there is spreading and fusion of podocyte foot processes along most of the glomerular filter. Although these foot process abnormalities are seen with most causes of nephrotic range proteinuria, with minimal change disease it is the principal or only abnormality on the kidney biopsy. Figures 66-4 and 66-5 depict a normal glomerulus and a glomerulus with minimal change disease, respectively.

Treatment

Minimal change disease is treated with the general nonpharmacologic and pharmacologic measures for glomerular disease, especially sodium restriction, RAAS blockade, and diuretics. In addition, minimal-change disease is the most responsive glomerular disease to corticosteroids. In children, because steroid therapy leads to remission in more than 90% of patients, and because minimal change is the most common cause of the nephrotic syndrome, most children with nephrotic syndrome do not undergo kidney biopsy. Instead, they are empirically treated with steroids, and those that respond are diagnosed with "steroid-sensitive nephrotic syndrome," which is assumed to be due to minimal change disease. Children with nephrotic syndrome are empirically treated with prednisone 60 mg/m^2/day for 4 to 6 weeks.[14] Adults are administered prednisone 1 mg/kg/day (maximum 80 mg) or 2 mg/kg/every 2 days (maximum of 120 mg) for at least 4 weeks. The goal of treatment is complete remission, defined by negative proteinuria. In children the response rate is excellent, with complete remission in 50% of children after 1 week and >90% after 4 weeks of steroids.[45] In adults a complete remission takes longer, with 50% of adults responding to steroids by 8 weeks and an additional 10% to 25% responding by 16 weeks.[46] Patients who achieve complete remission carry the added diagnosis of "steroid-sensitive disease." Patients who achieve complete remission must remain on steroids but can begin to reduce the steroid dose 2 weeks later, tapering over 2 to 5 months in children, and tapering by 6 months in adults. Patients who do not respond to therapy by 16 weeks are considered "steroid-resistant," and steroids can be tapered off more rapidly.

Among patients who achieve complete remission, relapse is unfortunately common. More than 80% of "steroid sensitive" patients will experience a relapse of proteinuria within 6 to 12 months, requiring repeat steroid therapy, usually at a lower dose and shorter duration compared to the initial presentation. Some patients relapse infrequently, while others relapse frequently and can carry the diagnosis of "steroid-dependent" disease.

Chronic steroid therapy can result in problematic side effects such as growth retardation, insomnia, avascular necrosis of long bones, acne, polyphagia, and mood disorders. For patients developing side effects from chronic steroid therapy, or who decline initial steroid therapy, or who develop "steroid-resistant" disease, a second-line treatment for minimal change is required. Spontaneous remissions do occur, but often require years, and the risk of persistent nephrotic syndrome for years while hoping for a spontaneous remission is greater than the risks of medical treatment. Alternative medications to steroids include cytotoxic chemotherapy (cyclophosphamide or chlorambucil), calcineurin inhibitors (cyclosporine or tacrolimus), mycophenolic acid, or rituximab.[15] Based on limited data, these second-line therapies achieve remission in about 75% of patients, and none is clearly superior. One limitation of calcineurin inhibitors is that, if remission is achieved, then another recurrence is very common as the medications are tapered down.

Adults who initially have steroid-sensitive minimal change disease, and then become steroid-resistant on a subsequent relapse of disease, often have focal and segmental glomerulosclerosis (FSGS) on a second biopsy, which forms the basis for speculation that some forms of minimal change disease are part of a spectrum with FSGS.[47]

Focal Segmental Glomerulosclerosis

Focal segmental glomerular sclerosis (FSGS) is a histopathologic description on kidney biopsy, and the clinical difficulty is determining the cause. The most common causes of FSGS are primary (idiopathic), which appears to result from a circulating factor in blood that has not been identified, secondary FSGS due to large number of conditions, and heritable/genetic FSGS, most of which involves genes that control the podocyte cytoskeleton.[48–50]

In the case of primary FSGS, we presume the cause is a circulating factor because, when these patients have lost kidney function and undergo kidney transplantation, FSGS can recur within the new kidney within hours to days, and these patients sometimes respond just as rapidly to plasmapheresis. Although the rapid recurrence and rapid remission with pheresis argue for the existence of a circulating factor, the identity of this factor remains elusive.

Secondary FSGS can be caused by a few drugs, namely pamidronate (but only at very high doses) and heroin (but only in selected outbreaks, suggesting a contaminant within batches of drug but not the opioid itself), but drug-induced FSGS is fairly rare. Most secondary FSGS is caused by "adaptive" changes over many years in patients who have a mismatch between body size and the number of glomeruli (so either a person is too large, or the number of glomeruli are too few). This is sometimes called the "Brenner" hypothesis of FSGS, and is described using terms such as "maladaptation to reduced nephron mass." Clinical examples of adaptive FSGS include large body size due to morbid obesity or high-protein diets with anabolic steroids, or reduced glomerular number due to congenital hypoplasia, premature birth, sickle-cell disease, and nephrectomy. Not all patients with these clinical conditions will develop secondary FSGS over years-decades, but the risk is significantly increased. There is also an aggressive form of secondary FSGS seen among patients with untreated HIV infection due to podocyte damage, which we call HIV-associated nephropathy.

A third cause of FSGS to consider is genetic. Mutations in more than 20 genes have been identified from families with FSGS, and the unifying theme is that these genes all appear to regulate the podocyte cytoskeleton, consistent with the podocyte's unique shape, with protrusions that end in many hundreds of foot processes. The inheritance pattern of genetic FSGS varies with patient age and gene and can be recessive (especially in children), dominant (especially in adults), or maternal (such as mitochondrially inherited FSGS with seizures).

A special variant of genetic FSGS, the inheritance of G1/G2 risk alleles of *APOL1* among people of West African ancestry, may explain why FSGS is roughly 4× more common in Black adults compared to non-Black adults. Similar to sickle cell anemia, the GI and G2 "risk alleles" of the *APOL1* gene help resist a serious infection (African sleeping sickness due to trypanosomes) and these alleles are principally found among people of West African ancestry. Only one allele is needed to kill trypanosomes and resist sleeping sickness (much like the benefit of one sickle cell allele in resisting malaria), but people who inherit two copies of *APOL1* risk alleles are at increased risk for biopsy-proven focal and segmental glomerulosclerosis (much like the severe phenotype from two sickle cell alleles). When we look at the frequency of the G1 and G2 alleles among Black adults, and the magnitude of increased risk these alleles confer for FSGS, these alleles can mathematically account for all of why FSGS is 4× more common among Blacks than people of European descent. The mechanism by which these APOL1 risk alleles cause FSGS is still uncertain and a focus of research. Testing patients for these APOL1 risk alleles is of uncertain value and is not routine, because the lifetime risk of FSGS with two copies of G1 and/or G2 is only 4% to 5%,[51] which is much lower than nearly 100% penetrant Mendelian mutations, and with no mechanism for why these *APOL1* alleles cause disease, and no treatment thus far, a positive test will not change a patient's treatment.

FSGS is uncommon in children with nephrotic syndrome but precise statistics are uncertain because, as described in the section on minimal change disease, children who respond to steroids are presumed to have minimal change disease and do not undergo kidney biopsy. In adults, FSGS was historically the second most common cause of nephrotic syndrome after membranous, but the incidence of FSGS has been increasing, and for the last 20 years has been the most common cause of biopsy-proven nephrotic syndrome in US adults.[52]

Clinical Presentation

Patients with FSGS, whether primary, secondary, or genetic, present with proteinuria, which can be sub-nephrotic or nephrotic. Hypertension, microscopic hematuria, and impaired kidney function may be seen in up to half of all patients. If nephrotic range-proteinuria is present, some patients will have normal serum albumin and minimal to no edema, while others will have the full nephrotic syndrome. These clinical differences are the first step in making the clinically difficult decision of who may have primary FSGS and therefore should consider immunosuppressive therapy. Patients with primary FSGS are more likely to have the full nephrotic syndrome, while patients with secondary FSGS are most likely to have nephrotic-range proteinuria without nephrotic syndrome. Features on kidney biopsy can also help distinguish primary versus secondary disease. The gold-standard for primary FSGS is whether the disease recurs shortly after kidney transplantation and responds to plasmapheresis therapy.

Histology

As the name would suggest, FSGS under light microscopy is defined by sclerosis of glomeruli that is focal (involving some, but not all of the glomeruli), and segmental (involving only a part of the glomerulus). Figure e66-6 depicts a normal glomerulus (A) compared to a glomerulus with focal segmental glomerulosclerosis (B). There are histologic subtypes, including the tip lesion (in which sclerosis involves only the tip of the glomerulus furthest from the vascular pole), a cellular variant, and a collapsing variant (in which at least one capillary loop within a glomerulus appears to have collapsed inwards upon itself). Immunofluorescence in FSGS reveals focal and segmental deposition of IgM and C3 in areas of sclerosis, which is considered to be nonspecific trapping of proteins. Electron microscopy will show effacement of foot processes, similar to minimal change disease. Foot process effacement will be partial instead of diffusely complete in patients who have clinically milder disease, such as secondary causes of FSGS, or sub-nephrotic primary FSGS. Similar to the overlap on clinical presentation, it is difficult to definitively distinguish primary versus secondary FSGS based on histology, and the combined use of clinical features with histology is often needed for a final decision.

By virtue of the fact that FSGS is focal, the histopathology can be completely missed on kidney biopsy if an inadequate number of glomeruli are sampled. For instance, if FSGS affects 20% of all glomeruli in a particular patient (which would likely be mild disease), then an inadequate biopsy with only one glomerulus would have an 80% chance of missing the diagnosis, a biopsy with two glomeruli would have a 64% chance of missing the diagnosis, and a biopsy with 20 glomeruli would have a 0.8%[20] chance, which is a 1.1% chance of missing the diagnosis. These figures apply to FSGS and other focal glomerular diseases, and help illuminate why the KDIGO guidelines recommend that an "adequate" kidney biopsy for patients with glomerular disease should have at least 20 glomeruli.[14]

Treatment

The treatment of FSGS is controversial because of a paucity of data from randomized, placebo-controlled trials, as well as the difficulty of distinguishing primary versus secondary FSGS. Patients who are diagnosed as primary FSGS and have the nephrotic syndrome are candidates for a trial of immunosuppression. Those with secondary FSGS have treatment directed at the underlying, secondary cause (eg, weight loss if secondary to morbid obesity). All patients with FSGS, whether primary or secondary, and whether nephrotic or subnephrotic, are treated with conservative measures as described above for general glomerular disease.[49]

If immunosuppression is undertaken for primary FSGS, the KDIGO recommendation is corticosteroid therapy with prednisone (or prednisolone) at the same dose and duration as used for minimal change disease.[14] The response rate to steroids is both slower and less frequent than with minimal change. The median time to complete remission is 3 to 4 months, although 5 to 9 months may be needed in some patients. By 16 weeks, if a patient has not achieved at least partial remission, defined by a 50% reduction in proteinuria, then steroids are tapered off and the patient is considered "steroid resistant." Based on large retrospective studies, 50% to 70% of patients will achieve at least a partial remission on steroids. Some of this response may include patients with spontaneous remission, which can occur, but we do not have definitive data from placebo-controlled trials to know the relative efficacy of corticosteroid therapy.

If a patient has "steroid resistant" FSGS, or has contraindications to corticosteroids due to diabetes, bone disease or mood disorders, then the preferred alternative to corticosteroids is calcineurin inhibitors. Cyclosporine with a therapeutic trough of 100 to 175 ng/mL (mcg/L; 83 to 146 nmol/L), or tacrolimus with a therapeutic trough of 5 to 10 ng/mL (mcg/L; 6.2 to 12.4 nmol/L), for at least 6 months, achieves similar benefits, with a partial or complete response in about 70% of patients.[53,54] However, about 50% of patients who respond will relapse shortly after tapering the calcineurin inhibitor. Other steroid-sparing therapies, which are discussed above in the treatment of minimal change disease, include mycophenolate, rituximab, and cyclophosphamide, but for FSGS the data on these therapies are less robust than the data for calcineurin inhibitors.[15,55]

In patients who achieve complete remission the prognosis is good, with less than 10% progressing to ESKD within 10 years.[49] At the other end of the spectrum, among patients who are resistant to therapy, 50% progress to ESKD within 10 years, with a highly variable rate, sometimes within months, sometimes many years. Patients with severe proteinuria (more than 10-15 g/day), high serum creatinine at diagnosis, steroid resistance, and interstitial fibrosis on kidney biopsy are more likely to progress to ESKD rapidly. In patients who undergo kidney transplantation for ESKD, FSGS will recur in 40% of kidney allografts soon after transplantation.[49] Patients who had rapidly-progressing FSGS in their native kidneys are more likely to have recurrence in their transplant. Genetic FSGS should not recur after transplantation. Genetic FSGS is more common in children or adults from families with a clear pattern of inheritance, and among adults with primary FSGS who do not have a family history, the benefit of routine genetic testing has not been established.[15]

Membranous Nephropathy

Membranous nephropathy (MN) is one of the most common causes of nephrotic syndrome in adults, with peak incidence between ages 30 and 50 years. Autoantibodies against a podocyte antigen, the M-type phospholipase A2 receptor (PLA2R), have been found in 70% to 80% of patients with primary membranous nephropathy.[56] Antibodies to PLA2R are sufficiently specific that many experts now recommend presumptive diagnosis of primary MN without the need for kidney biopsy. Autoantibodies against thrombospondin type-1 domain-containing 7A have been found in 3% to 5% of cases of MN,[57] but these autoantibodies are also found in secondary membranous due to cancer.[58] Autoantibodies against neutral endopeptidase (NEP) have been described in rare cases of neonatal membranous nephropathy.

About 25% of adults and 80% of children have secondary causes of membranous nephropathy. In the United States, the most common secondary causes are autoimmune diseases (lupus), chronic infections (hepatitis B, hepatitis C, or syphilis), neoplasms (large-sized adenocarcinomas such as lung, breast, stomach, colon, or prostate), and medications used historically for rheumatoid arthritis (gold or penicillamine). Malaria and schistosomiasis are common causes of secondary membranous in other parts of the world. A full list of other, rare secondary causes of MN is beyond the scope of this chapter. It is important to distinguish primary versus secondary MN with history, exam, serologies, and age-appropriate cancer screening, because primary MN is treated with aggressive immunosuppression, while some of the secondary causes of MN (cancer, infections) can dramatically worsen if immunosuppression is administered.

Clinical Presentation

Most patients with membranous nephropathy present with heavy proteinuria (exceeding 3.5 g/day) and the nephrotic syndrome with minimal to no nephritic features. Urine microscopy often reveals lipiduria and oval fat bodies, but microscopic hematuria is present in fewer than 25% of patients, and red cell casts are quite rare. The onset of nephrotic syndrome is usually insidious, in contrast to the fulminant onset of minimal change disease. If nephrotic syndrome is present, the presenting symptom can be deep vein thrombosis or pulmonary embolism due to hypercoagulable state. The incidence of renal vein thrombosis varies from 5% to 62% and can be asymptomatic (especially if unilateral) or may cause gross hematuria with loin pain.

Histology

Kidney biopsy under light microscopy reveals glomeruli with normal mesangium and normal cellularity. The hallmark feature of membranous nephropathy is sub-epithelial deposits on light microscopy and electron microscopy (see **Fig. e66-7**), but in early stages of MN these deposits can be difficult to see, glomeruli may appear normal on light microscopy, and electron microscopy is required to be able to see the deposits and make the diagnosis. Over time, subepithelial deposits of MN become surrounded by newly synthesized glomerular basement membrane, and this extra basement membrane looks like "spikes" of the GBM under light microscopy, especially when visualized with special stains to enhance basement membrane components (either Periodic acid–Schiff [PAS] or Jones stains). The subepithelial deposits, which do not stain, eventually become large enough to look like "holes" within the GBM. In later stages of MN, the GBM becomes progressively thickened, and the mesangium becomes sclerotic. Immunofluoresence in primary MN will show granular deposits of IgG and C3 along the GBM, and if the GBM also stains positively for PLA-2R antibodies, then primary MN is confirmed. If the GBM stains negatively for PLA-2R, or stains positively for thrombospondin type-1 domain-containing 7A, then secondary MN due to adenocarcinoma is likely. If the GBM stains positively for IgG, IgM, IgA, antibody light chains and more ("full house"), then the MN is secondary to class V lupus. Serologies for lupus are usually positive in these patients, but in some cases the serologies do not become positive until 1 to 3 years later.

FIGURE e66-7

Diagram (*A*) and electron micrograph (*B*) depicting membranous nephropathy. Electron microscopic features of membranous nephropathy include numerous subepithelial electron-dense deposits that correspond to the immune complexes seen by immunofluorescence microscopy, and effacement of podocyte foot processes. (Reproduced, with permission, from Reisner H. Pathology: A Modern Case Study. 2nd ed. New York: McGraw Hill; 2020. https://accessmedicine.mhmedical.com/ Accessed September 12, 2022.)

Treatment

All patients with primary and secondary MN should be treated with conservative measures. For secondary MN, additional treatment is directed at the underlying cause; if due to adenocarcinoma, then surgical resection can result in remission, and if due to a virus or parasite, then treating the infection is indicated. For primary MN, additional treatment involves the decision of whether to use immunosuppression. The risks and benefits of immunosuppression involve an assessment of the clinical severity of disease, for which treatment may be worth the risk, balanced with the likelihood that a spontaneous remission will occur, in which immunosuppression is not worth the risk. Up to 30% of patients with spontaneous MN experience spontaneous remission, but this takes time, often 1 to 3 years after disease onset. The likelihood of spontaneous remission correlates with milder disease. Of patients who do not have a spontaneous remission within two years, half have persistent proteinuria with long-term preservation of kidney function, while the other half have gradual loss of kidney function to ESKD over 5 to 10 years, and these are the patients who will benefit most from immunosuppression. A predictive algorithm has been developed which incorporates the level of proteinuria, initial creatinine clearance, and the slope of kidney function decline over 6 months.[59] To simplify the decision tree somewhat for the purposes of this chapter: (1) if proteinuria is less than 4 g/day, then immunosuppression is not initiated, and spontaneous remission after 1 to 3 years is likely. (2) If proteinuria is between 4 and 8 g/day, wait six months and monitor to see if a spontaneous remission is beginning, and if not, then consider starting immunosuppression. (3) if proteinuria is more than 8 g/day with the full nephrotic syndrome, and GFR is greater than 30 mL/min/1.73 m^2, immunosuppression is recommended. The logic here is that a kidney with GFR above 30 mL/min/1.73 m^2 is still “worth saving,” the nephrotic syndrome is severe enough that complications are likely, and the 10-year algorithm predicts progress toward ESKD if untreated. (4) if proteinuria and the nephrotic syndrome have already caused a complication such as life-threatening pulmonary embolism, then start immunosuppression. There are additional nuances to this decision tree, but this detail is beyond the scope of this chapter.

Immunosuppressive treatment for MN is different than minimal change and FSGS in that corticosteroid treatment by itself has no benefit. The three options for immunosuppression in primary MN are cytotoxic therapy, calcineurin inhibitors, and rituximab, each in conjunction with a small or moderate amount of corticosteroid. Cytotoxic therapy involves a modified “Ponticelli protocol” of alternating corticosteroids and oral cyclophosphamide for 6 months.[60] For the first month, KDIGO recommends starting with a very high dose of 1,000 mg/day intravenous methylprednisolone for 3 days followed by oral prednisone 0.5 mg/kg for 27 days. For the second month, patients receive oral cyclophosphamide at 2.5 mg/kg/day with prednisone 10 mg to avoid steroid withdrawal symptoms. This cycle is repeated on months 3 to 4 and months 5 to 6, followed by a steroid taper.[15] Calcineurin inhibitors for MN are administered twice daily for 6 months or longer, either cyclosporine 3.5 mg/kg/day aiming for a trough of 125 to 225 ng/mL (mcg/L; 104 to 187 nmol/L), or tacrolimus 0.05 to 0.075 mg/kg/day aiming for a trough of 3 to 10 ng/mL (mcg/L; 3.7 to 12.4 nmol/L). Rituximab for MN is most often infused at two doses of 1,000 mg IV, 2 weeks apart, and repeated at 6 months if there is no remission based on a combination of proteinuria and serologic monitoring.

Lastly, in addition to being an acceptable serologic test for the diagnosis of primary MN without need for kidney biopsy, the titre of anti-PLA-2R antibody can assist with decisions on immunosuppression.[61] Antibody titre tend to change several months before changes in proteinuria. For patients with intermediate proteinuria who are being monitored for 6 months in the hope of spontaneous remission, persistent nephrotic syndrome would argue to start immunosuppression, but if the anti-PLA-2R titre is clearly falling, then proteinuria should remit soon, and a few more months of monitoring may provide the proof to avoid unnecessary immunosuppression. Alternatively, in patients with severe disease who received immunosuppression but still have persistent nephrotic syndrome 6 months later, raising the question of treatment failure, a falling antibody titre provides reassurance that the treatment is working remission of proteinuria will come soon. Lastly, in patients who achieve complete remission, the return of a positive anti-PLA2R titre occurs several months prior to a recurrence of proteinuria to help plan for repeat immunosuppressive therapy.

Dysproteinemias and Amyloidosis

Dysproteinemia is the general term for a monoclonal antibody in serum that is causing disease within an organ. Dysproteinemias can cause glomerular disease (nephrotic, nephritic or both), and dysproteinemias can also cause non-glomerular kidney disease. Instead of focusing on how dysproteinemias can cause MPGN, this section provides an overview of how dysproteinemias can affect the kidney in many ways. A dysproteinemia is suggested by finding an increased level of a monoclonal immunoglobulin in serum, but the diagnostic difficulty is that most monoclonal immunoglobulins in serum are not causing any harm to the kidney or any organ, leading to the term monoclonal gammopathy of unknown significance (MGUS). The incidence of MGUS increases with age, and in one seminal study from the Mayo clinic, MGUS was found on serum protein electrophoresis with immunofixation in 3.2% of patients older than 50, 5.3% of patients old than 70, and 7.5% of patients older than 85.[62] Based on these numbers, in many patients with kidney disease, finding a serum monoclonal antibody is less likely to explain the cause of kidney disease, and more likely to be a coincidental MGUS with a kidney disease caused by something else. A patient diagnosed with MGUS can, over years, progress to having smoldering multiple myeloma or overt myeloma, which frequently affect the kidney. Along the spectrum between MGUS and myeloma are patients who have a monoclonal antibody in serum with reassuring kidney biopsy, but they have new proteinuria or progressive kidney failure of unclear cause. On kidney biopsy, sometimes the monoclonal antibody is binding with high affinity to kidney tissues, in which case we use the term monoclonal gammopathy of renal significance (MGRS).[1] There are roughly 10^{15} different potential antibodies in the human repertoire, each with different amino acid sequence, polypeptide folding, and antigen-binding characteristics, and these differences determine how (and whether) the kidney will be attacked by a dysproteinemia. The severity of kidney disease also depends on the rate at which an antibody is being produced by a clone of B-cells. The most common patterns of kidney disease with dysproteinemias are myeloma cast nephropathy, light-chain deposition disease, and amyloidosis.

Myeloma Cast Nephropathy

Myeloma cast nephropathy tends to present with rapid loss of kidney function. Patients are often oliguric, and sometime anuric. Cast nephropathy occurs when a B-cell clone is synthesizing excess light chains, which are filtered across the glomerulus and reach high concentration in the urine as overflow proteinuria. If conditions are just right, then the light chains will precipitate within the tubules and form insoluble casts that plug up the nephron. Precipitation into casts depends on the biophysical properties of the antibody (some amino acid sequences will fold/organize into casts much more readily than others), and proteins tend to precipitate more often when concentrated, and under a certain salt concentration or acidity. Clinically, a patient will suddenly stop making urine, as if they have a urine obstruction, but the bladder will be empty. The obstruction is not within the urine collecting system, but is higher up, within every tubule of each nephron within the kidney.

Pathology

Kidney biopsy reveals intraluminal proteinaceous casts in the distal nephron. The casts are usually acellular, homogenous with multiple fracture lines. Persistence of casts produces giant cell inflammation and tubular atrophy. Immunofluorescence should confirm the casts stain with light chains, and the staining should be kappa or lambda but not both (confirming a monoclonal proteinuria).

Treatment

To reverse the process of precipitation of antibodies within the distal nephron, treatment includes (a) aggressive hydration to increase fluid flow with nephrons, which reduces the concentration of antibody within the nephron so cast formation is less likely; (b) immediate chemotherapy against plasma cells or mature B-cells, to reduce the amount of antibody that is being produced; (c) consideration of plasmapheresis, although the clinical data suggest that the only patients who might benefit from pheresis are those that respond to chemotherapy. It is not certain whether the pheresis itself confers significant benefit; (d) hemodialysis to replace kidney function until a patient responds to chemotherapy, and the intra-tubular casts have time to dissolve.

Light-Chain Deposition Disease

Light-chain deposition disease tends to present with significant proteinuria, and often the full nephrotic syndrome. Progressive renal failure is the rule. Response to traditional chemotherapy is poor. On kidney biopsy, LCDD involves deposition of light chains into glomeruli (mesangium and GBM) and tubular basement membranes but spares the kidney's blood vessels (in contrast to AL amyloidosis). The deposits appear pale on H&E stain, are PAS positive (like diabetes), and are Congo-red negative (unlike Amyloid). On immunofluorescence the GBM and tubular BM will have granular staining with either kappa or lambda light chain, but not both (because the disease is from a single cancer clone, with only one light chain), and may show granular, electron dense material on EM.

Amyloidosis

Amyloidosis occurs when proteins, because of a specific amino acid sequence, or a peptide cleavage event, fold abnormally into beta-pleated sheets that are insoluble and deposit between cells, producing atrophy and cell death. There are three general type of amyloidosis: AL amyloid, AA amyloid (which occurs in inflammatory states like rheumatoid arthritis or familial Mediterranean fever) and hereditary amyloid. AL amyloid is rare among dysproteinemias because only a small fraction of antibodies have amino acid sequences that favor folding into B-pleated sheets, but AL a common cause of systemic amyloidosis.

The clinical presentation of renal amyloidosis is nephrotic syndrome, often very severe, without nephritic features. Blood pressure may be low due to deposition of amyloid within the systemic vasculature. Ecchymoses are common because minimal pressure can induce the systemic blood vessels to bleed. Depending on the amino acid sequence, amyloid will have a proclivity to particular organs, which can include the heart, liver, peripheral nervous system, gastrointestinal tract, tongue, and gums. On kidney biopsy amyloid can form nodules (like diabetes) but the amyloid nodules will not stain well with PAS, whereas diabetic nodules stain strongly with PAS. Congo red stain shows green birefringence of amyloid under polarized light. On immunofluorescence, light chain amyloidosis (see **Fig. e66-8**) will stain with either kappa or lambda, but not both (because of the monoclonal nature of cancer). On EM amyloid may have small nonbranching fibrils 7.5 to 10.0 nm wide, of variable length and periodicity.

FIGURE e66-8

Light chain amyloidosis. (*A*) By light microscopy, amyloidosis causes replacement of normal glomerular architecture by amorphous acidophilic (eosinophilic) material (hematoxylin and eosin stain, H&E stain). (*B*) Immunofluorescence microscopy of amyloid demonstrates deposits of monoclonal immunoglobulin light chains (anti-lambda). (Reproduced, with permission, from Reisner H. INFLAMMATORY GLOMERULAR DISEASE

The basic presentation of inflammatory or proliferative glomerular diseases is usually nephritic, but the clinical findings can vary widely. A mild case of IgA, for example, may have only microscopic hematuria, with no proteinuria, no hypertension, and no loss of kidney function over 20 years. At the other end of the spectrum, rapidly progressive glomerulonephritis with Goodpasture's syndrome can progress from onset of disease to ESKD in weeks, and if untreated has a 90% chance of mortality. The most common specific diagnoses in inflammatory glomerular disease are discussed in detail below.

Immunoglobulin A Nephropathy

IgA nephropathy uses the suffix "pathy" of a noninflammatory disease but has the clinical symptoms of an inflammatory/proliferative glomerulonephritis in ~ 95% of patients. IgA is also known as Berger's disease, after the French physician who first described the disease. It is the most common primary glomerulonephritis in the world and accounts for 10% of patients with ESKD in many countries. The prevalence of IgA varies from a high of 45% of all glomerulonephritis in Asia to 30% to 40% in Europe and 10% to 15% in the United States. Within the United States, the diagnosis is rare among Black patients with glomerulonephritis, but as high as 35% among Native Americans in New Mexico.[63] These differences in IgA prevalence around the world are often ascribed to genetics, or possibly environment, but the differences in prevalence also reflect regional variations in who should undergo kidney biopsy. For example, if one region performs kidney biopsy only if patients who have glomerular hematuria and more than 1 g proteinuria, while another region performs kidney biopsy in all patients with glomerular hematuria regardless of proteinuria, the latter will have a "higher" prevalence of IgA. These types of differences in disease detection are known to confound data on disease prevalence throughout the Health Sciences. The true prevalence of IgA including mild disease is not known. One study from Japan suggested the prevalence of clinically silent IgA may be as high as 16% of the population.[63]

The diagnosis of IgA can only be made by kidney biopsy (detailed histology below) and is defined by dominant or co-dominant staining of IgA on immunofluorescence. There are no serologic tests for IgA, and the levels of serum immunoglobulins are unhelpful. Like many glomerular diseases the cause of IgA can be primary or secondary. Primary disease is caused by a multi-hit process that begins with errors in post-translational glycosylation of IgA heavy chains. Specifically, the hinge region (roughly in the middle of the IgA heavy chain) should have galactose residues added to O-glycans as part of post-translational modification of amino acids in that region of the protein. Patients with IgA fail to add galactose residues to a variable number of O-glycans in the region. These defects in glycosylation are hereditary, but are not sufficient to cause disease, and are only step 1 in the "multi-hit" process. In the next step, in most but not all patients, these aberrant, galactose-deficient O-glycans are perceived as "non-self" and result in IgG auto-antibodies directed against the hinge region of IgA. In the third step, if the levels of both galactose-deficient IgA and the IgG auto-antibody are high enough, and the binding affinity of IgG auto-antibodies is strong, then IgG-IgA immune complexes will form within the circulation. These can be detected in patients with IgA nephropathy but are still not sufficient to cause disease. In the last step, these circulating immune complexes bind to the GBM during glomerular filtration and in some but not all patients, these complexes become entrapped within the mesangium and elicit an antibody-mediated, inflammatory cascade.[64]

Clinical Presentation

Primary IgA nephropathy commonly presents in the second and third decades of life but can occur at any age. Clinical severity can vary tremendously. Most patients present with asymptomatic microscopic hematuria, with variable degrees of proteinuria, hypertension, and decreased kidney function. Ten years after diagnosis, approximately 10% to 20% will reach ESKD, and after 20 years this is true for 30% of patients. Predictors of eventual progression to ESKD are persistent hypertension, GFR that is already decreased, obesity, and especially the magnitude of proteinuria.[63] Instead of subtle microscopic hematuria, some patients present with synpharyngitic gross hematuria, in which a respiratory infection (or rarely gastrointestinal infection) results in a flare of hematuria.[63] Patients often seek medical care for their reddish-brown or "coca-cola" colored urine, and a workup of the many causes of gross hematuria eventually leads to a diagnosis of IgA. The timing of a flare of hematuria at the time of pharyngitis is different from the 2-week delay after pharyngitis that is characteristic of post-infectious glomerulonephritis. Rarely, patients with IgA nephropathy present with the nephrotic syndrome, or may present with rapidly-progressive glomerulonephritis (described later in this chapter), in which kidney function declines over weeks instead of years.

Secondary IgA nephropathy is caused by liver disease and several bowel diseases, and as with all secondary glomerular diseases, treatment should be directed at the underlying cause. Circulating IgA antibodies are normally cleared by the liver. Increased levels of circulating IgA in patients with liver disease result in IgA nephropathy in some but not all patients, probably via a multi-hit process (but not identical to that of primary IgA). IgA secondary to liver disease usually causes hematuria without progressive CKD and disappears after liver transplantation or other treatment to improve liver function. Inflammatory bowel disease also increases the levels of circulating IgA because it is a secreted antibody from lymphoid tissue in the gastrointestinal tract. When IgA arises in patients with Crohn's disease, multiple case reports describe that remission of Crohn's leads to remission of IgA.[65] Similarly, in patients with celiac disease who develop IgA nephropathy, restriction to a gluten-free diet results in remission of disease.

Histology

As mentioned above, the diagnosis of IgA can only be made by kidney biopsy. Testing for auto-antibodies is not commercially available and, as described above, would not be sufficiently predictive due to the multi-hit process of pathophysiology. The Oxford histologic classification system provides a uniform approach to biopsy evaluation in primary IgA, and its predictive value has been demonstrated in multiple patient cohorts.[66] Light microscopy typically reveals mesangial cell proliferation (which means more than three mesangial cells in a glomerular capillary loop, in a biopsy section of typical thickness), but in mild disease, the glomeruli can appear normal (see **Fig. e66-9**). Rarely, in patients with the clinical syndrome of RPGN, glomerular crescents will be found (crescents and RPGN are discussed later in the chapter). On immunofluorescence, the glomerular capillary loops will stain brightly with IgA, most often more brightly than any other antibody, but in some cases the staining will be co-dominant. On electron microscopy, the mesangium will contain electron-dense deposits, which are sometimes seen in the sub-endothelial GBM, contiguous with these areas of mesangium.

FIGURE e66-9

Treatment

Patients with mild IgA disease, defined as microscopic hematuria, normal proteinuria, normal blood pressure and normal kidney function, may be treated with the nonpharmacologic measures described above in the Treatment of Generalized Glomerular Diseases, and closely monitored over many years. Patients with proteinuria >0.5 g/day, regardless of blood pressure, are treated with full conservative measures including ACEIs or ARBs. The goal blood pressure is at least lower than 130/80 mm Hg and possibly lower, as described previously. For patients with proteinuria greater than 1 g/day despite 3 to 6 months of optimal care with ACEIs or ARBs, additional therapy is recommended. In the 2012 KDIGO guidelines, 6 months of daily corticosteroids were the preferred additional therapy, but studies have shown high rates of serious adverse events from steroids.[67] The current recommendation is that patients with persistent proteinuria >1 g/day undergo individual assessment of the risks and benefit of corticosteroids, and consider referral to a clinical trial site for one of many experimental treatments that are currently under evaluation.[64] A kidney biopsy showing crescents is not, by itself, sufficient to recommend use of steroids or other aggressive therapy.

IgA vasculitis, formerly known as Henoch-Schönlein Purpura (HSP), is a rare disease that most often presents in children or young adults. It is difficult to study rare diseases in children, but the current hypothesis is that the pathophysiology is very similar to primary IgA as described above. The symptoms of IgA vasculitis are the same as primary IgA, with glomerular hematuria and a variable degree of proteinuria, hypertension, and loss of kidney function. In addition, IgA vasculitis causes a skin rash on the thighs, buttocks and low abdomen, with a variable degree of abdominal pain. The skin rash and abdominal pain lead to medical evaluation, and eventually to the diagnosis. The supposition is that the skin and GI symptoms are caused by deposition of the same circulating IgA-IgG antibody complexes that deposit in the mesangium. Skin biopsy, if performed, will show leukocytoclastic vasculitis that stains predominantly with IgA. On kidney biopsy, the histology under light microscopy, immunofluorescence, and electron microscopy resembles all the findings of primary IgA nephropathy. Treatment of IgA vasculitis should probably be the same as for IgA nephropathy, with a decision for systemic steroids based on whether proteinuria persists after maximal conservative therapy for 3 to 6 months.

Post-Infectious Glomerulonephritis

Post-infectious glomerulonephritis (PIGN) usually occurs in healthy children who are 5 to 15 years of age, and is uncommon in children under age 2, or in adults over the age of 50. Most often it is caused by a “nephritogenic” strain of streptococcus in patients with bacterial pharyngitis, or less commonly with a skin infection (impetigo). There are specific “nephritogenic” strains of Group A, beta-hemolytic Streptococci: types 1, 4, and 12 (for pharyngitis), and types 49 and 2 (for impetigo). About 14 days after the infection, the immune response to infection with a nephritogenic strain results in antibody-mediated glomerular damage. These antibodies may bind with streptococcal antigens that have already deposited on the glomerular filter to form immune complexes that activate an inflammatory response (in-situ immune complex formation), or immune complexes may form with streptococcal antigens within the circulation and then deposit on the glomerular filter (circulating immune complex formation), or the antibodies may be intended for bacterial antigens but are cross-reacting with the glomerular antigens in the absence of streptococci (molecular mimicry). The evidence is strongest for in-situ immune complex formation, but by any of these three mechanisms, antibody-antigen complexes will activate complement and recruit neutrophils and monocytes, leading to a brisk inflammatory glomerulonephritis.

Many other infections can cause infectious glomerulonephritis with a similar biopsy and similar features. Instead of occurring 2 weeks after streptococcal pharyngitis, these other infections are smoldering chronic diseases such that, when humoral immunity begins to kick in 2 to 6 weeks later, the infection is still present. As such, these are not strictly speaking, post-infectious, and we use the term “infectious glomerulonephritis” instead, but the basic mechanisms and clinical presentations are similar. Examples of smoldering infections that can cause infectious glomerulonephritis include sub-acute bacterial endocarditis, chronic Staphylococcus epidermidis infection of a ventriculo-peritoneal shunt, or chronic bacterial liver abscess.[68]

Clinical Presentation

With PIGN there is often enough hematuria for patients to see coca-cola colored urine, similar to patients presenting with synpharyngitic IgA nephropathy, but unlike IgA, all symptoms including the hematuria that changes urine color begin 2 weeks after the infection. All patients with PIGN will have microscopic hematuria, and there are varying degrees of other nephritic syndrome features. Urine microscopy will reveal dysmorphic red cells and often red cell casts, or mixed red and white cell casts. Hypertension is common and can be dramatically severe in children, including emergency room visits for hypertensive emergency with seizures. Proteinuria is usually less than 3 g/day but is sometimes nephrotic-range, and as such PIGN is one of the glomerular diseases that can sometimes have an overlap of nephritic with nephrotic features. Kidney function is usually decreased and falling at the time of presentation. Other laboratory tests include decreased serum C3 complement (because antibody-antigen complexes are activating complement, which uses up C3 in serum faster than it can be synthesized), increased anti-streptolysin O titers after a nephritogenic streptococcal pharyngitis, or increased anti-DNAse B titers after a nephritogenic bout of impetigo. The diagnosis can be made based on these clinical features and lab tests. Kidney biopsy is not indicated unless the patient has prolonged hematuria, proteinuria, or depressed C3 level, in which case the purpose of kidney biopsy is to rule out other types of glomerulonephritis such as lupus, RPGN, or MPGN.[68]

Overall, the long-term prognosis of PIGN is very good in children. Diuresis usually begins 7 to 10 days after acute onset. Kidney function returns to baseline within 3 to 6 weeks in more than 95% of patients. Gross hematuria lasts for 1 to 2 weeks, and proteinuria usually resolves within 6 months in more than 90%. Microscopic hematuria may persist for up to 2 years. Most children will have no detectable kidney disease in the long term. Adults, on the other hand, do not heal as well as children and are less fortunate. As many as 50% of adults will have persistent proteinuria, hypertension, and kidney insufficiency, with eventual progression to end-stage kidney failure. These adult patients are examples, as described in the discussions of general glomerular disease pathophysiology earlier in the chapter, of how an episode of acute glomerulonephritis can lead to an inflammatory cascade that persists, even after the initial cause has resolved.

Histology

If performed, kidney biopsy reveals hypercellular glomeruli with proliferation of mesangial and endothelial cells, and infiltration of neutrophils, monocytes, and eosinophils. The infiltrate will be prominent within glomerular capillary loops and the mesangium, consistent with where antibody-antigen complexes are depositing. Glomerular crescents may be seen and if more than 30% of glomeruli have crescents, along with a reduction of 50% in kidney function, then the PIGN is causing RPGN.[68] Immunofluorescence examination reveals diffuse granular deposits of IgG and C3 along the GBM and in the mesangium (**Fig. e66-10**).

FIGURE e66-10

Acute post-infectious glomerulonephritis. Immunofluorescence reveals diffuse granular deposits of IgG and C3 along the GBM and in the mesangium. (Reproduced, with permission, from Reisner H. Treatment

For a patient whose infection took place weeks ago, antibiotics are of no benefit and only create the risks of side effects. Treatment of post-infectious glomerulonephritis is supportive and is directed at hypertension from sodium retention due to the nephritic syndrome. Because the hypertension is due to low-renin sodium retention, ACEIs and β-blockers are less effective at controlling blood pressure, while diuretics and calcium channel blockers are more effective. In patients with crescentic disease on biopsy, steroids and/or immunosuppressive agents can be considered, but unlike other causes of RPGN, the efficacy and safety of these agents has not been established for post-infectious disease,[68] and for variants of infectious glomerulonephritis caused by smoldering, chronic infections, the benefit of immunosuppression must be carefully balanced against the risk of exacerbating the infection.

Membranoproliferative Glomerulonephritis

Historically, membranoproliferative glomerulonephritis (MPGN) has accounted for 7% to 10% of all cases of biopsy-confirmed glomerulonephritis and has been the third or fourth leading cause of ESKD among patients with glomerular diseases. MPGN is a “pattern of injury” based on histology, rather than a specific disease. In the last 10 years, the entire classification scheme for MPGN has changed, mainly due to advances in our understanding of the very complex pathophysiology of C3-related diseases, and of refinements in our appreciation of monoclonal disorders of renal significance. Formerly classified as MPGN type 1, or type 2 or type 3, the new classification scheme for MPGN is as follows:

> (1) Immune complex MPGN, which is usually due to mixed essential cryoglobulinemia from chronic hepatitis C infection. Sometimes, the immune complex MPGN is caused by a monoclonal light or heavy chain gammopathy, in which case only one type of antibody will stain under immunofluorescence.
>
> (2) Complement-mediated MPGN, which is usually a C3 glomerulopathy. These are rare diseases in which excess activation of the alternative complement pathway leads to deposition of C3 as the brightest stain on immunofluorescence of kidney biopsy. The alternative complement cascade can be overly activated by many different proteins and stimuli. Methods for diagnosing the cause of C3 glomerulopathy, and decisions for optimal treatment, are subjects of rare-disease clinical research and are beyond the scope of this chapter. In very rare cases, a distinct type of complement mediated MPGN is found on kidney biopsy. C3 dense deposit disease is diagnosed based on the pathognomonic finding of a dense, ribbon-like glomerular basement membrane on electron microscopy. Dense deposit disease, unfortunately, responds poorly to current treatments, and frequently recurs after kidney transplantation.

Immune complex MPGN in patients with hepatitis C is caused by mixed-essential cryoglobulinemia, which develops in some but not all patients with chronic hepatitis C infection. A cryoglobulin occurs when antibodies within the serum crosslink and precipitate into a gel of protein, particularly at temperatures colder than core body temperature (cryo = cold). A cryoglobulin can precipitate from the serum into various tissues (possible the skin, heart, kidneys, lungs, joints, GI track or brain), where the antibody precipitate can be large enough to impede capillary blood flow, and the crosslinked antibodies can also signal an inflammatory response.

Clinical Presentation

Immune-complex MPGN due to hepatitis C cryoglobulinemia is a nephritic or an overlap nephritic-nephrotic syndrome. A classic presentation is a patient who presents in the winter, when colder hands and feet will favor cryoglobulin formation, with a severe rash in the legs and hands, arthralgias of the hands, and nephritic syndrome with an active urine sediment on microscopy, hypertension, kidney failure, edema, and proteinuria that can be nephrotic-range. Kidney biopsy will show mesangial and variable endocapillary cell proliferation with circumferential extension of the mesangium into the subendothelial space of the capillary wall (mesangial interposition or mesangialization), resulting in thickening of the peripheral capillary wall. On silver stain, there is a "double contour" in the capillary walls (tram tracking), corresponding to reduplicated subendothelial lamina densa (**Fig. e66-11**).

FIGURE e66-11

Immune complex MPGN due to monoclonal gammopathies is one of the monoclonal gammopathies of renal significance.[1] Much less common than hepatitis C–mediated MPGN, in these patients a monoclonal antibody is being produced by an overt or subclinical B-cell neoplastic disorder. The monoclonal antibody is occasionally a cryoglobulin, different than the "mixed essential" cryoglobulin described above, in which the antibody binds to itself at temperatures lower than 37°C to form a cryoglobulin. In other cases the monoclonal antibody is not a cryoglobulin, but when it binds to antigen, the result is an immune complex cascade that leads to MPGN. The clinical presentation of these monoclonal disorders is usually a nephrotic syndrome with mild hypertension and occasional but infrequent microscopic hematuria,[69] but nephritic features can be present, depending on the degree of inflammatory response elicited by the particular monoclonal antibody.

Treatment

All MPGN patients can be treated with maximally tolerated conservative therapy. Immune complex MPGN due to hepatitis C cryoglobulinemia should be treated, as expected, by eradicating the virus. Until 5 to 10 years ago, this was accomplished by a year of treatment with interferon/ribavirin, with only modest viral remission and significant side effects. The development of direct anti-viral therapy over the last 10 years has made viral remission highly successful, and with few side effects. If hepatitis C cryoglobulinemia is causing an RPGN, then urgent treatment is required, and in addition to viral eradication, immunosuppression with corticosteroids and either rituximab or cyclophosphamide is used to arrest production of the causal antibodies.[70] Immunosuppression will make hepatitis C titres flare, and so immunosuppression must be coupled with anti-viral therapy. For immune complex MPGN due to monoclonal disorders, treatment is directed at the B-cell or plasma cell clone that is creating the antibody, and therapy is often a collaboration with colleagues from hematology-oncology.[71] Treatment of the C3 glomerulopathies with regimens including rituximab, mycophenolate mofetil and corticosteroids has been described, as has the use of terminal complement blockade with eculizumab. These treatments are generally informed by expert opinion, largely based on case series.[72]

Hereditary Glomerulonephritis (Alport's Syndrome)

Alport's is not an inflammatory glomerular disease, but it presents with nephritic syndrome, and understanding the pathophysiology of Alport's syndrome will help clinicians appreciate the most severe form of inflammatory glomerulonephritis due to anti-GBM antibodies as discussed below. Alport's syndrome is rare and affects about 1 out of every 50,000 newborns. Mutations arise or are inherited in the genes that encode for the alpha-3, alpha-4, or alpha-5 subunits of type IV collagen. Mutations in any of three separate genes that encode these three subunits can cause Alport's syndrome. In ~ 80% of patients, the mutation is within the alpha-5 subunit on the X chromosome, leading to severe disease in males. In 10% to 15% of patients, the inheritance is autosomal, due to mutations in the alpha 3 or alpha 4 subunits, which are encoded by separate genes arising from the same promoter on the long arm of chromosome 2. In less than 5% of patients, a causal mutation in these three genes was not identified.

The backbone of the glomerular basement membrane is formed from heterotrimers of these three proteins, so depending on the severity of the amino-acid change, the GBM will be weakened, prone to leaking albumin and blood across the GBM, and glomerulosclerosis will gradually ensue over a few decades. Microscopic hematuria begins during early childhood, followed by proteinuria and decreased kidney function as a teenager, and then ESKD between 20 and 40 years old. Less severe mutations can present as glomerulonephritis in later decades. Many patients with X-linked Alport's syndrome also have sensorineural deafness, because the alpha-5 subunit of type IV collagen is required for the basement membrane heterotrimers in the inner ear.

On kidney biopsy, light microscopy will reveal focal and segmental glomerulosclerosis, or global glomerulosclerosis, with "foam" cells (lipid laden macrophages and podocytes). Foam cells are not specific for Alport's and have been described in primary FSGS. Over time, kidney function is lost due to glomerulosclerosis, and sometimes this is mistaken as primary FSGS on biopsy. Immunofluorescence reveals absent GBM staining with an antibody to the alpha-5 subunit of type IV collagen. Mutations of alpha 3 and alpha 4 subunits also alter the filament structure enough to disrupt alpha-5 staining, so one antibody can "detect" mutations in any of the three subunits. On electron microscopy, the glomerular basement membranes will be thin in early disease (GBM thickness increases with age and can vary depending on how the GBM is sliced, perpendicular or angled, so pathologists make this measurement carefully). Over time the GBM becomes excessively thick, with splitting and fraying that is sometimes described as a basket-weave appearance.

There is no specific treatment. Conservative measures for glomerular disease may help slow the rate at which Alport's reaches ESKD. Transplantation is the best treatment. There are reports of anti-GBM nephritis after transplantation, but this is quite rare and was largely confined to patients with a large deletion of the alpha 5 subunit who made no protein, such that their transplanted kidney contained a new protein that was "not self."

Rapidly Progressive Glomerulonephritis (RPGN)

Before describing the last few specific diagnoses of glomerular disease, which are lupus nephritis, ANCA-associated vasculitis, and anti-GBM nephritis, we should introduce the term RPGN, for rapidly progressive glomerulonephritis. RPGN is a subset of nephritic syndrome in which patients are losing at least 50% of kidney function in less than 6 weeks (and usually faster). On kidney biopsy, all patients with RPGN have glomerular crescents, which are necessary to make the diagnosis of RPGN. Crescentic GN and RPGN are interchangeable terms for the same patient: the former term describes the kidney biopsy, and the latter describes the nephritic syndrome with rapid loss of kidney function. **Figure e66-12** illustrates a typical glomerular crescent, which is initially made of parietal glomerular epithelial cells (podocytes are the visceral epithelial cells and are not part of these crescents;

parietal epithelial cells are normally located on the other side of Bowman's space and have different biological properties than podocytes). As time progresses, inflammation from RPGN recruits macrophages and then fibroblasts into a cellular crescent. As fibroblasts secrete extracellular matrix it transitions into a fibro-cellular crescent, and eventually an entirely sclerotic glomerulus. Cellular crescents should respond to aggressive immunosuppression and enable salvage of that glomerulus. During the transition to fibrocellular crescents, salvaging a glomerulus with immunosuppression becomes increasingly difficult with aggressive chemotherapy, and once the crescent is sufficiently fibrous, the glomerulus and thus the entire nephron will be lost.

FIGURE e66-12

Crescentic glomerulonephritis with a large cellular crescent composed predominantly of proliferating epithelial cells (PAS stain). (Reproduced, with permission, from Reisner H. Pathology: A Modern Case Study. 2nd ed. New York: McGraw Hill; 2020. https://accessmedicine.mhmedical.com/ Accessed September 12, 2022.)

The cause of RPGN/crescentic GN is classified according to the staining of the glomerulus by immunofluorescence. First, if the glomerular capillary loops have a *granular antibody staining pattern* on immunofluorescence, then the cause of RPGN is an immune complex disorder, most often lupus nephritis. At lesser frequencies, one of the previously described immune complex glomerular diseases can cause RPGN, including hepatitis C cryoglobulinemia, monoclonal gammopathies causing MPGN, infectious glomerulonephritis, or IgA nephropathy. Second, if the glomerular capillary loops have *negative staining* with all common antibodies on immunofluorescence, then the cause of RPGN is a "pauci-immune" disorder, almost always due to ANCA-associated vasculitis. Lastly, if the glomerular capillary loops have a *linear staining pattern* on immunofluorescence, usually with IgG and only one of the light chains, then the cause of RPGN is anti-GBM glomerulonephritis, also called Goodpasture's disease.

Two more concepts related to the causes of RPGN should be discussed; namely, the range of severity of kidney disease, and the range of organs that are affected. First, anti-GBM nephritis almost always presents as an RPGN, but the other causes of RPGN listed above with granular or pauci-immune staining can also cause a milder glomerulonephritis that does not change serum creatinine by 50% in less than six weeks. There is a spectrum of disease. Second, all forms of RPGN listed above can affect just the kidney, in which case we use the term "renal vasculitis," or can affect the kidney as well as other organs, such as the lungs, heart, brain or nervous system, in which case we use the term "systemic vasculitis." Pulmonary-renal syndrome is an example of systemic vasculitis. In patients with systemic vasculitis, even if the symptoms in the kidney are less severe than the symptoms in another organ (such as alveolar hemorrhage from pulmonary vasculitis), kidney biopsy is more sensitive, and therefore has a higher yield for making the diagnosis.

Lupus Nephritis

The most common cause of RPGN with granular immune deposits is systemic lupus erythematosus (SLE), a multisystem, autoimmune disease with antibodies directed against a wide variety of cellular constituents. SLE can affect the kidney in many other ways or can affect other organs and never affect the kidney. SLE is a syndrome of autoimmunity, not a single disease that follows the same molecular mechanism in every patient. The immune system in patients with SLE can attack one or more of the following organ systems: skin, joints, serous membranes, heart, peripheral nervous system, central nervous system, white blood cells, red blood cells, platelets, skin, and kidneys. When discussing lupus nephritis, we are referring to primary SLE, not lupus secondary to drugs such as hydralazine and procainamide, which almost never causes kidney disease.

SLE is diagnosed more often in women than men (roughly 6:1 ratio), and in the United States, SLE is most often diagnosed in young Black women, but the significance of this is uncertain because, as some experts have noted, SLE is quite rare in sub-Saharan Africa. Experts speculate that a complex predisposition involving both environment and genetics underlies SLE, but a clear molecular mechanism remains elusive. A person whose first degree relatives have SLE is 10 to 20 times more likely to develop SLE, but this is far less than Mendelian frequency. More than 100 susceptibility genes have been identified, many of which involve the HLA-locus. Changes in B-cell function, T-cell function and the cytokine milieu are all implicated in the pathogenesis of SLE.[73,74]

Depending on definitions, kidney involvement is found among less than 50% of patients with SLE, but when it arises it is one of the most serious complications. The diagnosis of lupus nephritis relies on a combination of clinical features, laboratory results from blood and urine, and histopathologic appearance on kidney biopsy. Lupus can affect the entire body in many different patterns, and it can also affect the kidney in many different patterns of disease. The easiest way to understand the breadth possible symptoms and treatments of lupus nephritis is to start with the World Health Organization classification, which is based on kidney biopsy (see **Table e66-1**). Each of the WHO classes of lupus nephritis on kidney biopsy has a typical clinical presentation, and the WHO class on kidney biopsy is instrumental in directing therapy.[75]

Patients with sub-nephrotic proteinuria and either WHO class 1 or 2 on biopsy are treated with conservative therapy. Patients with WHO class III and class IV on biopsy are considered to have “proliferative lupus nephritis,” and are treated aggressively. Proliferative lupus typically presents with microscopic hematuria with an active urine sediment under microscopy (dysmorphic red cells +/− red cell casts), sub-nephrotic proteinuria, and rising serum creatinine (the full nephritic syndrome), combined with a variable number of extra-renal manifestations of lupus, such as arthralgias, serositis, anemia, or a sun-sensitive rash. Anti-nuclear antibody titre is almost universally elevated, which is a sensitive but not specific test (so a negative test argues against disease, but a positive test is not enough to confirm the diagnosis). Serologies with high specificity for proliferative nephritis include antibodies to **d**ouble **s**tranded DNA (anti-**ds** DNA) or to the Smith antigen (anti-Sm). Serum levels of complement (C3, C4, or total complement CH50) are often low, because immune complex deposition is activating and consuming complement components. We do not consider class III and class IV mechanistically different, just part of a spectrum of proliferative lupus nephritis. Class III disease is defined as less than 50% of glomeruli affected and can present as RPGN but often has a milder nephritic syndrome, with mild-moderate extra-renal symptoms. Class IV disease, with greater than 50% of glomeruli affected, is the severe end of the spectrum; patients more often meet criteria for RPGN, and sometimes have pulmonary-renal syndrome. The division between class III and class IV based on +/− 50% glomerular involvement is arbitrary, especially given the small sample size of a kidney biopsy. In fact, while class III is “milder,” the long-term kidney-survival and patient survival data are similar or even a bit worse for class III disease, which may be the result of less aggressive treatment. In keeping with the notion that class III and IV diseases are not pathophysiologically different, the KDIGO recommendations for treatment of both classes of disease are very similar, with maximal conservative therapy, plus hydroxychloroquine, plus aggressive immunosuppression with corticosteroids and either intravenous cyclophosphamide or oral mycophenolate.

Remission in class III, IV, or V disease is based on stabilization or improvement in kidney function over 6 to 12 months and improvement in proteinuria to less than 0.5 g/day.[15] Some experts also desire absent microscopic hematuria for remission, but this is not part of the current definition. During the use of aggressive immunosuppression, similar to the use of terms in oncology, there is an “induction phase” with a goal of achieving remission, followed by a transition to “maintenance phase” immunosuppression for another 18 to 36 months when patients take either mycophenolate or azathioprine. With aggressive immunosuppression, the survival of patients with classes III and IV disease has improved during the last two to three decades to approximately 80% at 10 years. The major cause of death in people treated with immunosuppression is infection including sepsis. This illustrates the balance of risk and benefit. Immunosuppression prolongs life and prolongs kidney function but is also predisposes to life-threatening infections. Careful monitoring is required.

Recurrence of lupus nephritis is unfortunately common and can be surprising. A patient who initially presented with class III lupus can recur with class III but could also recur with class IV + V combined disease for which aggressive immunosuppression is needed, or with class II disease for which repeat immunosuppression would not be indicated. For this reason, patients with lupus nephritis undergo multiple kidney biopsies throughout the course of their disease.

ANCA-Associated Vasculitis

RPGN with pauci-immune staining on immunofluorescence is caused by ANCA-associated vasculitis. Similar to proliferative lupus nephritis, ANCA-associated vasculitis can also cause a milder nephritic syndrome that does not meet criteria for RPGN. Using the 2012 Chapel Hill Consensus on how to classify ANCA-disease, we sub-classify patients as having either granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), or eosinophilic granulomatosis with polyangiitis (EGPA). GPA was formerly called Wegner's granulomatosis, and EGPA was formerly called Churgh-Strauss, but these eponyms have fallen out of favor. ANCA-associated vasculitis is in fact, associated with autoantibodies, so the absence of antibody staining on biopsies may seem peculiar, and this simple observation is part of a complex pathophysiology of disease.[76] Anti-neutrophil cytoplasmic antibodies (ANCA) are found in 90% of patients with pauci-immune vasculitis, usually in association with high titres of autoantibodies to myeloperoxidase (anti-MPO) or proteinase 3 (anti-PR3). Serum complement levels are normal which, like the absence of staining on immunofluorescence, is peculiar among antibody-mediated diseases. Similar to the range of organ involvement in SLE, ANCA-associated vasculitis can be a renal-limited vasculitis that affects only the kidney, or can be a systemic vasculitis that affects the kidney as well as other organs of the body such as a pulmonary-renal syndrome.

With all of these complexities in mind, the 2012 Chapel Hill consensus proposed three clinical syndromes, each of which is most-often associated with a particular pattern of ANCA, a particular auto-antibody on ELISA, and a particular predisposition to involvement of organs in addition to the kidney (see **Table e66-4**).[15,77]

TABLE e66-4

Sub-Classification of ANCA-Associated Vasculitis

Disease	Pattern of ANCA	ELISA Auto-antibodies	Most Frequent Extra-Renal Organ Involvement	Less Frequent Extra-Renal Organ Involvement
GPA	C-ANCA on IF	Anti-PR3	90% also have respiratory involvement that ranges from sinusitis to pharyngitis to walking pneumonia to life-threatening alveolar hemorrhage. Because the presentation is smoldering, patients are often diagnosed with sinusitis or pneumonia for weeks to months before all the facts are put together. Most patients are more aware of their upper respiratory symptoms than they are of the more serious kidney symptoms until lab testing is performed.	Each of the following organ systems is affected in 40%-60% of patients: - skin (rash, often ears or nose, can erode the nasal bridge) - musculoskeletal (weakness, myalgias) - neurologic (mononeuritis multiplex, meaning a single peripheral nerve is affected, such as gaze deviation with CN VI, or foot drop with peroneal nerve) - gastrointestinal (ranging from decreased appetite and nausea to mesenteric vasculitis causing ischemia, with abdominal pain and bloody stools)
MPA	P-ANCA on IF	Anti-MPO	May be renal-limited disease. Each of the following organ systems is affected in 30%-60% of patients: - musculoskeletal (weakness, myalgias) - neurologic (mononeuritis multiplex like GPA) - gastrointestinal (like GPA)	- Upper respiratory / sinus involvement is quite rare. - Lower respiratory tract involvement with the appearance of pneumonia due to interstitial fibrosis or usual interstitial pneumonia is seen in roughly 30% of patients
EGPA	P-ANCA (but up to 50% are ANCA negative)	Anti-MPO	Invariably presents as asthma, and then astute health providers note asymptomatic nephritic syndrome. - neurologic (mononeuritis multiplex, see GPA).	Each of the following organ systems is affected in 50%-70% of patients: - skin (like GPA) - -upper respiratory (like GPA) - lower respiratory (like MPA) - musculoskeletal (like GPA) - gastrointestinal (like GPA)

WHO, Word Health Organization; ANCA, antineutrophil cytoplasmic autoantibody; GBM, glomerular basement membrane; GPA, granulomatosis with polyangiitis; EM, electron microscopy; CKD, chronic kidney disease; IF, immunofluorescence; LM, light microscopy; MPA, microscopic polyangiitis; MPO, myeloperoxidase; PAS, periodic acid–Schiff stain; PR3, serine protease-3; SLE, systemic lupus erythematosus; TMA, thrombotic microangiopathy; EGPA, eosinophilic granulomatosis with polyangiitis.

ANCA-associated vasculitis can also be a secondary disease due to various drugs such as etanercept, hydralazine, propylthiouracil, minocycline, or cocaine. Drug-induced ANCA-associated vasculitis most often causes high titre of anti-MPO, but can also cause simultaneous anti MPO with anti-PR-3, which does not occur with primary ANCA-associated vasculitis. Cocaine associated vasculitis is thought to arise from “cutting” the cocaine with levamisole, an anti-helminth drug in powder form that has affinity for many ion-channels and receptors at the molecular level, and complex effects on the immune system overall. Instead of aggressive immunosuppression, the best treatment is simple: cessation of the medication that is causing ANCA vasculitis.[77]

Treatment of Primary ANCA-associated vasculitis often relies on combined use of high-dose corticosteroids and cyclophosphamide, similar to inflammatory lupus nephritis. Unlike lupus nephritis, the alternative to cyclophosphamide is rituximab, not mycophenolate. In the 2020 KDIGO draft for glomerular disease, cyclophosphamide and rituximab carry equal weight for all sub-classification of ANCA-associated vasculitis, and the final choice of treatment depends on weighing the side effects and individual patient characteristics. Reasons to opt for rituximab include a desire for future fertility (especially in children and young adults), frail elderly patients, and possibly PR-3 disease. Reasons to opt for cyclophosphamide including a difficulty accessing rituximab, which must be administered at licensed infusion centers, and possibly severe RPGN with pulmonary-renal syndrome.[15]

Remission is clinically assessed by the absence of microscopic hematuria, which is different than lupus nephritis, in which remission is defined by resolution of proteinuria. With ANCA vasculitis, the optimal result is resolution of all features of the nephritic syndrome, but it is recognized that proteinuria may persist after active disease has resolved due to residual damage that has caused secondary glomerulosclerosis. Once remission is achieved as assessed by resolution of hematuria, patients are transitioned to maintenance therapy using azathioprine or rituximab. This is another difference with lupus nephritis, where maintenance therapy is usually mycophenolate. The optimum length of maintenance therapy is not known but is typically 2 to 3 years. Patients who had upper respiratory disease often received trimethoprim-sulfamethoxazole during this time, based on modest clinical trial data that this may reduce the frequency of future relapse.

Anti-Glomerular Basement Membrane Glomerulonephritis

RPGN with linear staining of antibodies on immunofluorescence is caused by anti-glomerular basement membrane (anti-GBM) nephritis. The disease occurs most often in young adult males, but anti-GBM nephritis can occur in both sexes at all age ranges. Anti-GBM nephritis arises when an autoantibody is directed against the alpha-3 subunit of type 4 collagen.[78] It is not certain what triggers the formation of these autoantibodies. In some cases, it is believed that another process damages the GBM, changing the way that type 4 collagen protein within heterotrimers has folded, uncovering an epitope on the alpha-3 subunit that is ordinarily buried. When this epitope, the NC1 domain of the alpha-3 subunit, is recognized as “not self,” antibodies form to directly attack this epitope, which damages the glomerular basement membrane. In animal models, progression from disease onset to ESKD can occur in less than two weeks, and while human disease may be a bit slower, it is nonetheless a fulminant process. There are no tests to predict who will develop disease, and so patients usually present only once the nephritic syndrome causes symptoms. A typical scenario might be an otherwise healthy young man, who feels horrid, seeks care in an emergency room, and learns he has kidney failure and might need dialysis immediately. Around half of patients (25%-60% in studies) will also have shortness of breath with a bloody cough due to lung involvement. Of the 3 staining patterns on IF, the linear pattern of anti-GBM nephritis is the least common cause of RPGN, but it is the most common among patients with pulmonary-renal syndrome. This is because the heterotrimers of collagen type 4 that make basement membrane in alveoli do not use the same 3 subunits as the kidney, but they do have one subunit in common, and that is alpha-3. Just as the auto-antibody attacks the alpha 3 subunit in the GBM, making holes that allow blood and protein to leak into the urine, the auto-antibody attacks the alveolar basement membrane, making holes that allow blood and protein to leak into the alveolar airspace. Clinically this is called “diffuse alveolar hemorrhage” and can suffocate gas exchange within the lungs.

The diagnosis of anti-GBM nephritis is made with a kidney biopsy showing necrotizing and crescentic glomerulonephritis on light microscopy, with linear staining for IgG along the glomerular basement membrane on immunofluorescence. Anti-GBM antibodies are detectable in the serum of the vast majority of patients.[79] Patients are treated with aggressive immunosuppression to stop new antibody formation. Steroids, cyclophosphamide, and plasmapheresis are recommended in all patients with a few exceptions. If patients have symptomatic disease only in the kidney, are already on dialysis, and had crescents in 100% of glomeruli on an adequate kidney biopsy, then treatment can be withheld. Plasmapheresis is continued for two weeks, or until the serum anti-GBM antibodies become negative.[14,79] Clinical recurrence of anti-GBM nephritis after kidney transplant has been reported and for this reason, transplantation should be delayed until the anti-GBM antibody is undetectable for at least 6 to 12 months.

CLINICAL BOTTOM LINE

A better understanding of the pathogenetic mechanisms leading to glomerular injury has led to marked improvements in the treatment of glomerular diseases. However, the glomerulopathies are a heterogeneous group of immune disorders with different clinical courses, prognoses, and responses to current immunologic and nonimmunologic therapies. The optimal treatment strategy for patients should be personalized based on the natural history and prognosis of their glomerular disease, and the risks and benefits of aggressive immunosuppression for that particular patient. Clinicians who wish additional involvement in the clinical care of patients with glomerular disease should consult the KDIGO guidelines.[14,15]

ABBREVIATIONS

ACE	angiotensin-converting enzyme
ACEI	angiotensin-converting enzyme inhibitor
ANCA	antineutrophil cytoplasmic autoantibody
ARB	angiotensin II receptor blocker
EGPA	eosinophilic granulomatosis with polyangiitis
ESKD	end-stage kidney disease
GBM	glomerular basement membrane
GFR	glomerular filtration rate
GPA	granulomatosis with polyangiitis
FSGS	focal segmental glomerulosclerosis
HCV	hepatitis C virus
HIV	human immunodeficiency virus
HMG-CoA	β-hydroxy-β-methylglutaryl-coenzyme A
LDL	low-density lipoprotein (cholesterol)
MPA	microscopic polyangiitis
MPGN	membranoproliferative glomerulonephritis
MPO	myeloperoxidase
NEP	neutral endopeptidase
NSAIDs	nonsteroidal anti-inflammatory drugs
PAS	periodic acid–Schiff stain
PR3	serine protease-3

PIGN	post-infectious glomerulonephritis
PSGN	post-streptococcal glomerulonephritis
RAAS	renin-angiotensin-aldosterone system
RPGN	rapidly progressive glomerulonephritis
SLE	systemic lupus erythematosus

SELF-ASSESSMENT QUESTIONS

1. Which of the following is more common in patients with nephritic syndrome compared to those with nephrotic syndrome?

   A. red blood cell casts

   B. edema

   C. hyperlipidemia

   D. hypercoagulable state

   E. proteinuria

2. Albuminuria above the normal threshold of ~ 30 mg/day (or 30 mcg/mg urine creatinine [3.4 mg/mmol creatinine]) is associated with

   A. increased all-cause mortality.

   B. increased risk of progression to ESRD.

   C. increased risk of fatal cardiovascular events.

   D. increased risk of nonfatal cardiovascular events.

E. all of the above.

3. Patients with nephrotic syndrome are commonly advised to

    A. restrict sodium intake.

    B. restrict potassium intake.

    C. initiate RAAS blockade at the maximum tolerated dosed.

    D. target blood pressure of less than 140/80.

    E. Options A and C only.

4. Which of the following may be used to reduce proteinuria for patients with glomerulonephritis?

    A. angiotensin-converting enzyme (ACE) inhibitor

    B. combined use of angiotensin-converting enzyme (ACE) inhibitor and angiotensin II receptor blocker (ARB)

    C. verapamil

    D. spironolactone

    E. A, C, and D

5. Use of statins in patients with glomerulonephritis has been proven to

    A. reduce LDL cholesterol and total cholesterol levels.

    B. reduce risk for cardiovascular disease.

    C. reduce renal function decline.

    D. reduce the proteinuria progression.

    E. all of the above.

6. Pediatric patients with minimal-change nephropathy often respond well to steroid therapy. Which of the following lesions is often found on kidney biopsy in patients who are resistant to steroid therapy?

    A. lupus nephritis

    B. focal segmental glomerulonephritis

    C. immunoglobulin A nephropathy

    D. membranous nephropathy

    E. membranoproliferative glomerulonephritis

7. Which of the following agents is/are often used as first-line therapy for inducing remission in patients with recently diagnosed minimal-change nephropathy?

    A. steroids

    B. steroids and cyclosporine

   C. steroids and azathioprine
   D. steroids and cyclophosphamide
   E. steroids and mycophenolate mofetil

8. Which of the following is correct regarding the use of cyclosporine for the treatment of minimal-change nephropathy?
   A. Cyclosporine is often effective in inducing remission during relapse.
   B. Cyclosporine is useful for patients who are steroid dependent.
   C. The disease-free period is not often sustained after therapy discontinuation of cyclosporine.
   D. Nephrotoxicity is a concern after long-term use.
   E. All of the above are correct.

9. Which of the following are risk factors associated with rapid kidney function decline in patients with focal segmental glomerulonephritis?
   A. severe proteinuria
   B. high serum creatinine concentration at initial diagnosis
   C. initial steroid resistance
   D. interstitial fibrosis on kidney biopsy
   E. all of the above

10. A patient with IgA nephropathy who has proteinuria of 0.5 to 1 g/day should be treated with
   A. ACE-i or ARB to control blood pressure and reduce urinary protein excretion
   B. fish oil
   C. steroid treatment
   D. cytotoxic agents
   E. mycophenolate mofetil

11. Which of the following is/are commonly considered when selecting the optimal treatment for patients with lupus nephritis?
   A. disease activity according to pathologic findings
   B. duration of symptoms
   C. extent of proteinuria
   D. history of medication non-compliance
   E. all of the above

12. Which of the following is frequently used for chronic maintenance treatment of lupus nephritis?
   A. systemic steroids
   B. cyclophosphamide

C. cyclosporine or tacrolimus

D. mycophenolate mofetil

E. fish oil

13. Annual eye examination for possible retinal toxicity should be conducted for patients receiving long-term use of which medication?

A. fish oil

B. cytotoxic agent

C. cyclosporine

D. mycophenolate mofetil

E. hydroxychloroquine

14. Which of the following therapies is recommended for maintenance therapy of severe ANCA-associated vasculitis with kidney involvement?

A. methotrexate

B. azathioprine

C. mycophenolate mofetil

D. rituximab

E. either B or D

15. In patients with nephritic syndrome 2 to 3 weeks after streptococcal pharyngitis the best treatment is

A. rapid administration of intravenous antibiotics.

B. tonsillectomy after pre-operative clearance is obtained.

C. intravenous steroid therapy to reduce inflammation.

D. symptomatic treatment only.

E. both A and C.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** The reliable identification of red cell casts on urine microscopy indicates a nephritic syndrome. All other options (edema, hyperlipidemia, hypercoagulable state, and proteinuria) are more characteristic findings in patients with the nephrotic syndrome.

2. **E.** While albuminuria can be a transient finding in patients with tubular injury, patients with persistent albuminuria (either >30 mg/day, or greater than 300 mcg/mg urine creatinine [34 mg/mmol creatinine]) have increased risks for multiple adverse outcomes, including all-cause mortality, fatal cardiovascular events, major nonfatal cardiovascular events, and progression to ESRD.

3. **E.** Conservative therapy of both nephritic and nephrotic syndrome includes restricting sodium intake (which helps reduce blood pressure and edema) and therapy with an ACEI or ARB at the maximally tolerated dose. Potassium is NOT restricted, because in general potassium is handled in the inverse manner as sodium, such that a high potassium diet tends to reduce blood pressure and edema. If concerning hyperkalemia develops that cannot be easily controlled by diuretics, only then is dietary potassium restricted. The target blood pressure is at least less than 130/80, and probably lower than 125/75 for patients with nephritic and nephrotic syndrome, so the target of 140/80 is incorrect.

4. **F.** Maximally tolerated ACEI or ARB therapy should be used, but dual blockade is no longer recommended due to the increased risk of adverse outcomes including AKI and significant hyperkalemia. Patients who cannot tolerate an ACEI or ARB due to allergies, or who need additional blood pressure control, can use a non-dihydropyridine calcium channel blocker (verapamil or diltiazem) which lowers blood pressure and has a modest anti-proteinuric effect. Dihydropyridine calcium channel blockers, while excellent at reducing blood pressure, tend to raise intra-glomerular pressure and do not have a beneficial anti-proteinuric effect. Spironolactone has a significant anti-proteinuric effect in diabetic glomerular disease and in patients with proteinuria of diverse causes.

5. **A.** Statin therapy reduces total cholesterol and LDL in patients with hyperlipidemia due to the nephrotic syndrome. Unlike conventional heart disease, however, we do not have clinical proof that these reductions in lipid levels lead to reduced major adverse cardiac events, so answer B is incorrect. Some studies have shown reduced proteinuria and reduced rates of CKD progression with statin therapy as described in answers C and D, but these benefits have not been consistent across studies and are not regarded as proven yet.

6. **B.** Because minimal change disease is a “pure” nephrotic syndrome, this question is asking, in children who fail steroid therapy, what is the most common cause of nephrotic syndrome. The overwhelming number of these children have focal and segmental glomerulosclerosis. If the same question were asked of adults who fail empiric steroid therapy, the biopsy findings would be a fairly close split of FSGS and membranous nephropathy; and overall, FSGS is slightly more common among adults.

7. **A.** Empiric therapy with steroids alone for 3 to 6 months. About 95% of children with nephrotic syndrome will respond to empiric steroids (without biopsy) with a complete remission. While the response rate is a bit lower in adults with biopsy-proven minimal change disease, the efficacy of steroids is still very high, and alternative therapies are considered only if the adult has relative or absolute contraindications to systemic steroid therapy.

8. **E.** Alternatives to steroid therapy include the calcineurin inhibitors tacrolimus and cyclosporine. Both calcineurin inhibitors are effective at inducing a remission of proteinuria, are good choices for patients who are steroid dependent or have contraindications to steroid therapy, but there are two caveats. If the calcineurin inhibitor is discontinued, nephrotic syndrome often returns fairly rapidly, but if the calcineurin inhibitor is continued for many years, nephrotoxicity becomes a long-term complication.

9. **E.** The absolute level of proteinuria has an adverse long-term prognosis for most glomerular diseases, which is why decreasing proteinuria is an acceptable therapeutic target. For most causes of kidney disease, it is also not surprising that the higher the creatinine at initial diagnosis, the worse the long-term outcome. Steroid responsiveness is much less common in FSGS than minimal change disease, and is associated with a better long-term prognosis, because steroid responsiveness means less proteinuria and often a slight improvement in serum creatinine; conversely, steroid resistance is an adverse prognostic sign. And the extent of tubule-interstitial fibrosis on kidney biopsy is for kidney diseases that range from diabetes to the most rare glomerular disease, one of the most reliable histopathologic findings of long-term prognosis. There are exceptions, due to sampling error, but in general, if the biopsy shows extensive fibrosis, a patient will not respond well to therapy.

10. **A.** The optimal treatment for IgA nephropathy may change in the next 2 to 10 years due to multiple ongoing clinical trials, but at present, patients with 1 g/day or less of proteinuria are treated with maximal ACEI or ARB and sodium restriction only. No immunosuppression is recommended. The benefit of fish oil has not been consistently demonstrated.

11. **E.** Systemic lupus is one of the most complex kidney diseases (and one of the most complex syndromes in medicine). The optimal choice of immunosuppressant depends on the pathology description on kidney biopsy, extra-renal symptoms, the extent of proteinuria, and whether the patient is likely to take daily oral therapy versus receipt of intermittent intravenous therapy.

12. **D.** Induction therapy for lupus nephritis depends on the findings on biopsy, and the goal is to achieve clinical remission within 3 to 6 months. After this, a patient is switched to maintenance therapy, usually with mycophenolate, or sometimes rituximab. Steroids are used sparingly if at all during the maintenance phase.

13. **E.** Hydroxychloroquine has a 1% to 10% chance of retinal toxicity, which is reversible if detected early, leading to medication discontinuation. Yearly ophthalmologic dilated exams are recommended for all patients who are prescribed hydroxychloroquine.

14. **E.** ANCA-associated renal vasculitis is treated slightly differently than lupus nephritis, in that the most common medication of the maintenance phase is azathioprine instead of mycophenolate. If azathioprine is not used, the second choice is rituximab.

15. **D.** In patients with nephritic syndrome 2 to 3 weeks after streptococcal pharyngitis, the most likely cause is post-infectious glomerulonephritis. This is sometimes clinically assumed in children, but in adults nearly all patients would undergo kidney biopsy to prove by histopathology. The optimal treatment for post-infectious GN is supportive. Antibiotics are not needed, because the infection is over. Steroids have not been shown to provide benefit in clinical studies, and are used only in selected patients based on expert assessment of an individual's risks versus benefits.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter e72: Evaluation of Neurological Illness

Melody Ryan; Stephen J. Ryan

KEY CONCEPTS

KEY CONCEPTS

① Accurate diagnosis of neurological disorders leads to effective pharmacotherapy.

② The clinical neurologic history and examination are the cornerstones of neurologic diagnosis and management.

③ History and examination should be modified for the pediatric patient as appropriate.

④ The neurologic history and examination are directed at localizing the disease process to derive a differential diagnosis.

⑤ After forming the differential diagnosis, appropriate testing helps pinpoint the correct diagnosis.

⑥ Accurate diagnosis leads to appropriate therapy and management of neurologic conditions.

⑦ Specific neurologic history and examination are useful for monitoring and evaluating the pharmacotherapeutic plan.

⑧ Lumbar puncture (LP) should only be performed when it can be done safely. Relative contraindications may include increased intercranial pressure, mass lesions, papilledema, and coagulopathies.

Watch the video entitled “The Neurologic Screening Exam” in AccessPharmacy by Daniel H. Lowenstein. https://accesspharmacy.mhmedical.com/MultimediaPlayer.aspx?MultimediaID=12986884

This nine-minute video provides a brief overview of the neurologic examination including all five components. This visual depiction will aid in student understanding of the examination. The information collected in the neurologic examination is used in the COLLECT and FOLLOW-UP steps in the patient care process.

INTRODUCTION

① ② Accurate diagnosis of neurological disorders leads to effective pharmacotherapy. This diagnosis is built upon history, a detailed neurological examination, and appropriate testing. To contribute most effectively to the care of patients with neurologic illness, one must understand the tools used in the diagnosis and management of these patients. In addition, clinicians must be able to gather their own data through patient history and targeted neurologic examination to ensure optimal pharmacotherapy. Despite technological advances and development of sensitive diagnostic tests, the clinical neurologic history and examination are still the cornerstones of diagnosis and management.[1]

SIGNS AND SYMPTOMS OF NEUROLOGIC DISORDERS

As in all of medicine, obtaining an accurate and complete history is of utmost importance in the evaluation of neurologic diseases. In many instances, the differential diagnosis can be made on the basis of the history, and the neurologic examination can be tailored to optimally evaluate the patient and confirm the diagnosis.[1] Open-ended questions allow the patient to provide the salient history without leading the patient toward preconceived diagnoses. Obtaining an accurate history may be difficult because a number of neurologic diseases potentially affect communication and memory. The details obtained from family or other observers, support and further expand patient reported history; additionally, family medical history can be helpful in diagnosis.[1] Through patient history, one can determine the main symptoms, location, onset (acute, subacute, or chronic), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses or risk factors for neurologic disease.[2] The history should also identify factors that might precipitate or ameliorate the symptoms.[2] Each patient complaint should be thoroughly investigated while taking the history. See Table e72-1 for questions to assist the clinician in obtaining the neurologic history.

TABLE e72-1

Questions to Ask Regarding Neurologic Symptoms

For each symptom:

- How would you describe the symptom (quality, severity)?
- Where is the symptom?
- When did it begin?
- Did it start suddenly or slowly?
- Has it stayed the same/improved/worsened?
- Does anything make the symptom occur?
- Does anything improve/worsen the symptom?

Data from Reference 2.

Special attention should be given to the medication history including current medications, doses, dosing schedule (times, relationship to other medications and meals), duration, and adherence. Adverse effects should be recorded in detail. Past and recently discontinued medications as well as any medications used previously, including reasons for discontinuation, to treat the main complaints are important. Clinicians should also consider if the patient's symptoms may be medication-induced.

③ Additional history is necessary for pediatric patients. The child should be allowed to provide as much history as he/she is developmentally able to do so. Because of the differing developmental stages of children, the amount of information the child is able to provide will vary with age. History may be obtained from the patients, guardians, or caretakers rather than the child in most cases.[3] Family history is particularly important because some pediatric neurological illnesses have a genetic cause.[3] History of the pregnancy, including maternal illnesses, medication or toxin exposures, and complications, should be noted.[3] The details of labor and delivery including duration, method of delivery, and complications may also be important.[3] Developmental history requires a comparison of the child's developmental stage to standard age-related developmental milestones.[3]

THE NEUROLOGIC EXAMINATION

④ A general physical examination is important because it can reveal evidence of systemic disease that may secondarily affect the nervous system.[2] The neurologic examination is one component of a complete general physical examination. A detailed neurologic examination is an extremely important tool for localizing a lesion within the nervous system.

The neurologic examination consists of seven main components: higher cortical function (mental status), cranial nerves, motor function, reflexes, cerebellar function, sensory function, and gait.[2] Table e72-2 describes the common approaches to assessing each of the seven domains and includes examples of the diseases in which abnormal findings are common. Readers are encouraged to consult other references to better understand the intricacies of the neurologic examination.[4,5]

TABLE e72-2

Neurologic Complaints and Corresponding Examination

Domain	Common Complaints	Example Tests or Assessment	Example Diseases with Abnormal Findings
Mental status	Confusion, forgetfulness, disorientation, speech difficulties, calculation difficulties, lack of facial recognition	While obtaining the history: general mental and emotional status, speech, memory, alertness, abstract reasoning, ability to follow commands (motor integration), ability to communicate	Dementias, stroke, metabolic encephalopathies
Cranial nerves	Blurred vision, ptosis, diplopia, anosmia, dysgeusia, dysarthria, dysphagia, facial asymmetry, tinnitus	Visual acuity, visual fields, eye movements, jaw strength, corneal reflex, facial symmetry, auditory acuity, gag reflex, shoulder and neck strength	Myasthenia gravis, stroke, ALS, Bell palsy
Motor function	Weakness, muscle cramps, muscle twitches, dropping items, muscle wasting, shaking	Motor strength with and without resistance tremors, atrophy, fasciculations, hypertonia, hypotonia	Stroke, myasthenia gravis, Parkinson disease, ALS, essential tremor
Reflexes		Deep tendon reflexes, plantar response, superficial cutaneous reflexes (eg, abdominal)	Stroke, spinal cord lesions, peripheral neuropathy, ALS, multiple sclerosis
Sensation	Tingling, numbness, burning, throbbing	Asymmetry or decreased sensation to pinprick, vibration, temperature, position	Stroke, peripheral neuropathy, spinal cord lesions
Cerebellar function	Unsteady gait, incoordination, tremor, speech abnormalities	Nystagmus, saccades, coordination (rapid alternating movements, finger-to-nose test, heel-to-shin test, finger tapping)	Stroke, posterior fossa tumors, alcoholic cerebellar degeneration
Gait	Unsteadiness, falls, tripping, freezing, slow gait, poor balance	Walking (tandem, on heels, on toes), standing (Romberg test—closing eyes tests proprioception)	Stroke, Parkinson disease, spinal cord lesions, multiple sclerosis

ALS, amyotrophic lateral sclerosis.

Data from Reference 2.

③ ⑤ ⑥ ⑦ The neurologic examination of pediatric patients should be adapted for age and developmental stage. Some adaptations of the standard examination techniques may include observing walking and playing for cerebellar and motor function or observing facial expressions, withdrawal, and responses to tactile sensory stimulation to assess sensory function.[6] Assessment of the weight, height, and head circumference and evaluated with reference to age- and gender-adjusted charts to identify any abnormalities.[7] In infants, the fontanels should be assessed for size and noted as to whether they are open or closed.[6] Specific pediatric neurology texts may be consulted for more detailed examination techniques for children.[3,8] The clinician must synthesize the results of the history and physical examination to arrive at an anatomic localization of the lesion and create a differential diagnosis, then use appropriate testing to help pinpoint the correct diagnosis. Accurate diagnosis leads to appropriate therapy and management of neurologic conditions. Repeat assessment of the history and examination are essential to customizing, monitoring, and evaluating a pharmacotherapeutic plan for an individual patient. For example, motor examination techniques can assist with evaluating the usefulness of Parkinson's disease therapy.

LABORATORY FINDINGS FOR NEUROLOGIC DISORDERS AND THEIR INTERPRETATION

⑧ Laboratory testing should be guided by the differential diagnosis for each patient; examples include treponemal testing for neurosyphilis, creatine kinase for myopathy, or vitamin B_{12} for peripheral neuropathy. One of the most neurologic-specific laboratory tests is the examination of the cerebrospinal fluid (CSF). Lumbar puncture (LP) is used to obtain CSF for further evaluation. It is used most often as an evaluation for markers of central nervous system infections, such as meningitis and encephalitis, but it is also useful in diagnosing subarachnoid hemorrhage or multiple sclerosis.[2] A long needle is inserted between the vertebrae of the lumbar spine and CSF is drained through the needle into collection vials (Fig. e72-1).[9] Opening pressure, blood cell count and differential, glucose concentration, total protein concentration, Gram stain, culture and sensitivity are measured routinely. Normal CSF laboratory values are given in Table e72-3.[9,10] A space-occupying lesion in the brain with mass effect is a relative contraindication to LP because herniation of the brainstem could result.[9,10] Before performing an LP, the patient should be checked for papilledema, which may indicate increased intracranial pressure. Additionally, coagulopathies are a relative contraindication because of the difficulty of compressing the site of the LP.[9]

FIGURE e72-1

Lateral decubitus position for lumbar puncture. The lumbar puncture needle is usually inserted in the L3-L4 or L4-L5 space. (*Adapted from Investigative studies. In: Simon RP, Aminoff MJ, Greenberg DA, eds. Clinical Neurology, 10th ed. New York: McGraw Hill; 2017.*)

TABLE e72-3

Commonly Obtained Cerebrospinal Fluid Measurements

Laboratory Value	Normal Value	Common Abnormalities	Abnormalities May Suggest
Color	Clear	- Xanthochromia - Turbidity	- Subarachnoid hemorrhage - Meningitis, encephalitis
Opening pressure	Less than 20 cm H_2O (2.0 kPa) (adults) Less than 28 cm H_2O ((2.7 kPa) (children)	Increased pressure	Hydrocephalus, cerebral edema
Protein	0.15-0.50 g/L	Increased protein	Trauma, infection, cerebral hemorrhage, subarachnoid hemorrhage, tumor
Glucose	30-60 mg/dL 1.7-3.3 mmol/L	Decreased glucose	Bacterial meningitis
White blood cells	Less than or equal to 5 cells/mm^3 (5 x 10^6/L)	Greater than 5 cells/mm^3 (5 x 10^6/L)	Meningitis, encephalitis
Red blood cells	0 cells/mm^3 (0 × 10^6/L)	Greater than 0 cells/mm^3 (0 × 10^6/L)	Subarachnoid hemorrhage, cerebral hemorrhage, traumatic lumbar puncture
Bacteria	0	Positive	Meningitis, encephalitis

Data from References 9,10.

ASSESSING NEUROLOGIC DYSFUNCTION

In addition to the history, neurologic examination, and laboratory examinations, certain imaging techniques and procedures may be essential in the diagnosis of neurologic disorders. Electroencephalography (EEG) records the electrical activity of the brain through electrodes placed on the scalp. The record is interpreted by observing the basic rhythms and waveforms, the symmetry of the recording, and abnormal electrical discharges.[9] It also may be used to assess the response to photic stimulation or hyperventilation. While used primarily in the diagnosis of seizures, EEG may be helpful in the evaluation of patients with altered mental status. In some cases, long duration (more than 24 hours) EEGs are obtained, but most are approximately 30 minutes in length.[9]

Evoked potentials can be used to measure the responses to electrical signals sent along various sensory pathways (visual, auditory, and somatosensory)[9] to examine conduction along those pathways. It may be helpful for localizing a lesion within sensory pathways and may be useful in evaluating conditions such as spinal cord lesions, hearing problems, and multiple sclerosis.

Electromyography (EMG) and nerve conduction velocities (NCVs) are used to assess the function of the peripheral nerves, neuromuscular junction, and muscles.[9] Measuring NCVs involves stimulating the nerve and recording the speed and amplitude of conduction of the impulse. It can be used to detect the presence of localized peripheral nerve injuries (eg, carpal tunnel syndrome) or diffuse neuropathies[9] and to look for neuromuscular junction disorders such as myasthenia gravis. Muscle dysfunction as a result of primary muscle disease or secondary to nerve injury can be assessed with EMG.[9] A needle is placed in the muscle to measure the resting and contractual electrical activity of the muscles to help diagnose peripheral neuropathies, amyotrophic lateral sclerosis, radiculopathies, and muscle diseases.[9]

DIAGNOSING NEUROLOGIC ANATOMIC ABNORMALITIES

Modern radiological imaging provides the clinician with several modalities to examine anatomical lesions of the nervous system itself and its vasculature. Computed tomography (CT) uses x-rays to produce images of thin "slices" of the brain.[9] It is currently available in most communities and is used to evaluate patients with intracranial disease. Because CT scans can be done relatively rapidly, they are used to evaluate patients in urgent circumstances (eg, acute ischemic stroke or hemorrhage) as well as less urgent assessment to identify tumors, hydrocephalus, atrophy, and other intracranial pathologies.[9] Intravenous contrast agents can provide imaging of vessel structure; they may also be used to identify areas of breakdown of the blood–brain barrier as the result of abscesses, other inflammatory conditions, aneurysms, tumors, or stroke.[9]

Magnetic resonance imaging (MRI) uses the magnetic properties of the hydrogen atom to produce computer-processed scans that provide improved anatomic detail compared with CT scans.[9] Advantages of MRI include better differentiating between white and gray matter and delineating lesions close to bone (brainstem and cerebellum) and has no radiation risk; however, it is not as readily available as CT, takes longer to perform, and is more expensive.[9] Patients who have metal implants or who have claustrophobia may be unable to undergo MRI. It has a proven advantage over CT in evaluating lesions in the posterior fossa and in detecting lesions in the white matter, such as plaques in multiple sclerosis.[9] MRI is also useful in the diagnosis of tumors and very early ischemic stroke (eg, diffusion-weighted imaging).

The cerebral circulatory system can be imaged or evaluated in a number of ways, depending on the type and location of the abnormality suspected. Imaging techniques can be used to identify local arterial stenosis, aneurysms, and vascular malformations.[9] Atherosclerosis of the extracranial arteries, a frequent cause of stroke, can be evaluated using ultrasonography (referred to as duplex sonography, carotid Doppler, or color-flow Doppler), magnetic resonance angiography (MRA), or computed tomographic angiography (CTA).[9] The intracranial arterial circulation can be evaluated using transcranial Doppler, MRA, CTA, or conventional dye angiography.[9] Each technique has its own advantages and disadvantages. Conventional dye angiography provides the best imaging of the smaller arteries of the cerebral circulation but is more invasive than the other measures.[9]

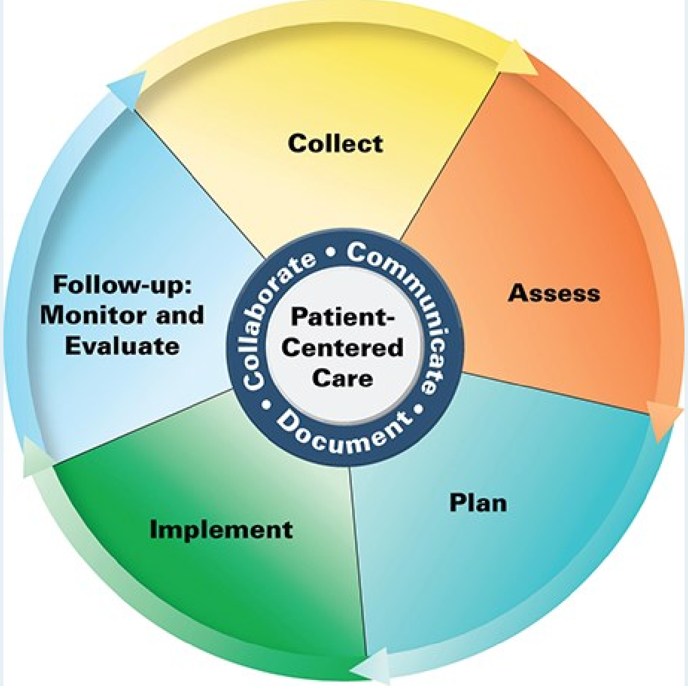
Imaging of the spinal canal and its contents can be accomplished by conventional dye myelography, CT myelography, CT, or MRI. Myelography refers to injecting a contrast agent via LP into the CSF, which is then imaged by x-ray (conventional dye myelography) or CT scan.[9] Myelography outlines the spinal cord and provides indirect information about the spinal cord, nerve roots, and surrounding structures. Direct imaging of the soft tissue of the spinal cord can be obtained via CT or MRI, although MRI provides higher quality images for structures around bones than CT because the bony structures cause the x-ray beams to scatter and produce artifacts on the images.[9] Compressive lesions and fractures can be identified by any of these methods; soft tissue lesions such as tumors, radiculopathies, and vascular malformations are better seen by MRI.[9]

SPECIAL PROCEDURES USED IN THE DIAGNOSIS OF NEUROLOGIC DISORDERS

Other imaging techniques, such as positron emission tomography (PET), single-photon emission computed tomography (SPECT), and functional MRI (fMRI), are considered tests of brain function. These tests are being studied extensively in epilepsy as well as in cerebrovascular disorders, cerebral tumors, movement disorders, and dementia.[9] Using a positron-emitting isotope, PET scans can image regional metabolic changes in the brain.[9] Measuring radiotracer uptake by tissues, SPECT scans assess cerebral blood flow. Although the resolution of SPECT is not as good as PET, it has use in localizing epileptic foci.[9] Functional MRI visualizes blood flow to focal areas of the brain by measurement differences in oxygenated blood concentrations to determine areas of greater activity.[9] Unlike PET scans, injection of radioactive isotopes is not necessary with fMRI. It is used for epilepsy and cognitive research.

PATIENT CARE PROCESS

Patient Care Process for Neurological Evaluation



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history (personal, family, birth, and developmental) (see section "Signs and Symptoms of Neurologic Disorders"; Table e72-1)
- Social history (eg, tobacco/ethanol use)
- Current and previous medications including nonprescription medications, herbal products, and dietary supplements (see section "Signs and Symptoms of Neurologic Disorders")
- Objective data
    - Neurologic examination (ie, higher cortical function, cranial nerves, motor function, reflexes, cerebellar function, sensory function, and gait) (see section "The Neurologic Examination"; Table e72-2)
    - Blood pressure (BP), heart rate (HR), height, weight
    - Laboratory examinations as appropriate for the differential diagnosis and possibly including examination of the CSF (see section "Laboratory Findings for Neurologic Disorders and Their Interpretation"; Table e72-3; Fig. e72-1)
    - Imaging studies as appropriate (eg, CT of head) (see section "Diagnosing Neurologic Anatomic Abnormalities")
    - Electrophysiology studies as appropriate (eg, NCVs, EMG, and EEG) (see section "Assessing Neurologic Dysfunction")

Assess

- Results of history and neurological examination
- Ability/willingness to obtain diagnostic testing (eg, insurance coverage, travel, undergoing invasive testing)
- Relative contraindications for lumbar puncture (see section "Laboratory Findings for Neurologic Disorders and Their Interpretation")
    - Relative contraindications for MRI (see section "Diagnosing Neurologic Anatomic Abnormalities")

- Emotional status (eg, presence of anxiety, depression)

Plan*

- Order appropriate diagnostic testing
- With established diagnosis, develop therapeutic plan (see disease-specific chapters)
- Monitoring parameters including efficacy and safety of any therapies; frequency and timing of follow-up
- Patient education regarding testing and diagnosis
- Referrals to other neurology specialists when appropriate (eg, memory disorders, stroke)

Implement

- Provide patient education regarding all elements of evaluation and treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence to any therapies
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Resolution of neurologic symptoms
- Presence of adverse effects of therapy
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate as needed

**Collaborate with patients, caregivers, and other healthcare professionals.*

CONCLUSION

Through collation and interpretation of the patient’s history, the neurologic examination, and other diagnostic tests, the clinician can fully understand the patient’s diagnosis and assessment. This comprehension allows the clinician to devise and monitor a pharmacotherapeutic plan that will be of most benefit to the patient with neurological disorders.

ABBREVIATIONS

ALS	amyotrophic lateral sclerosis
CSF	cerebrospinal fluid
CT	computed tomography
CTA	computed tomographic angiography
EEG	electroencephalography
EMG	electromyography
LP	lumbar puncture
MRA	magnetic resonance angiography
MRI	magnetic resonance imaging
NCVs	nerve conduction velocities
PET	positron emission tomography
SPECT	single-photon emission computed tomography

SELF-ASSESSMENT QUESTIONS

1. When evaluating a spinal cord lesion near a bone, the best imaging choice would be which of the following?
   A. Computed tomography (CT)
   B. Computed tomography angiography (CTA)
   C. Magnetic resonance imaging (MRI)
   D. Single-photon emission computed tomography (SPECT)
2. Lumbar puncture is most useful in the diagnosis of which of the following?
   A. Epilepsy
   B. Ischemic stroke
   C. Meningitis
   D. Parkinson's disease
3. Which of the following is a component of the neurologic examination?
   A. Abdominal rebound
   B. Gait
   C. Heart sounds
   D. Skin turgor
4. You are presented with the following cerebrospinal fluid (CSF) results: red blood cells = 400/mm^3 (400 × 10^6/L), white blood cells = 0/mm^3 (0 × 10^6/L), protein = 200 mg/dL (2.0 g/L), and xanthochromia. Which of the following is the best interpretation?
   A. Meningitis
   B. Multiple sclerosis
   C. Normal
   D. Subarachnoid hemorrhage
5. A patient presents with bilateral leg weakness, difficulty urinating, and numbness from the waist down. Which of the following is the best imaging technique to localize the lesion?
   A. Functional MRI of the spine
   B. MRI of the head

C. MRI of the spine

D. SPECT scan of the head

6. Elements of the pediatric neurologic history may include which of the following:

   A. Electroencephalography (EEG)

   B. Evaluation of developmental milestones

   C. Evaluation of respiratory signs

   D. Measurement of waist girth

7. When obtaining a history on an adult patient with recent numbness and tingling in her left arm, which of the following should be asked?

   A. What exacerbates the symptoms?

   B. Do you have shortness of breath that causes the symptom to occur?

   C. Were there any anomalies when you were born?

   D. When was your last menstrual period?

8. For which of the following patients could a lumbar puncture (LP) be performed?

   A. A patient with a coagulopathy

   B. A patient with symptoms of meningitis

   C. A patient with a space-occupying lesion with mass effect

   D. A patient with papilledema

9. A patient presents with headache and fever. CSF is obtained with the following results: red blood cells = 0/mm^3 (0×10^6/L), white blood cells = 215/mm^3 (215×10^6/L), protein = 200 mg/dL (2.0 g/L), and glucose 15 mg/dL (0.8 mmol/L). Which of the following is the best interpretation?

   A. Meningitis

   B. Multiple sclerosis

   C. Normal

   D. Subarachnoid hemorrhage

10. Which of the following neurologic examination techniques is most useful to diagnose a patient with myasthenia gravis?

    A. Reflexes

    B. Gait

    C. Cerebellar function

    D. Cranial nerve examination

11. A patient presents with decreased strength, reflex changes, and cranial nerve findings. Which of the following diagnoses should be considered?

    A. Meningitis

   B. Parkinson's disease

   C. Amyotrophic lateral sclerosis

   D. Peripheral neuropathy

12. You are asked to evaluate the pharmacotherapy of a patient with Parkinson disease. Which of the following neurologic examination techniques is best to assess the effects of the therapy?

   A. Cranial nerve evaluation

   B. Sensation testing

   C. Motor function evaluation

   D. Reflex testing

13. You are participating in a study of a new agent for cerebellar degeneration. Which of the following tests should be performed at study visits?

   A. Memory tests

   B. Reflex testing

   C. Visual acuity testing

   D. Finger-to-nose testing

14. You watch a neurologist perform the following tests: tandem walking, walking on tiptoe, Romberg testing. Which of the following is the neurologist likely assessing?

   A. Mental status

   B. Reflexes

   C. Cranial nerves

   D. Gait

15. A patient presents with a suspected small vessel vasculitic stroke. Which of the following tests provides the best images of the small vessels?

   A. Conventional dye angiography

   B. Computed tomography

   C. Magnetic resonance angiography

   D. Transcranial Doppler ultrasonography

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** MRI is better than CT for examining lesions near bone because the x-rays used in CT are scattered by the bony structures and produce artifact on the image. MRA is for examining the circulatory system. SPECT is a test of brain function. See section "Diagnosing Neurologic Anatomic Abnormalities" for a full discussion.

2. **C.** Lumbar puncture samples the CSF and is useful for diagnosing an infection such as meningitis in this space. See section "Laboratory Findings for Neurological Disorders and Their Interpretation" and Table e72-3 for more discussion of lumbar puncture findings.

3. **B.** The neurologic examination consists of the following domains: higher cortical function (mental status), cranial nerves, motor function, reflexes, cerebellar function, sensory function, and gait. See section “The Neurologic Examination” for a discussion of the examination and Table e72-2 for common findings.
4. **D.** A comparison of these CSF results to Table e72-3 demonstrates values consistent with subarachnoid hemorrhage. Red blood cells are elevated, protein is elevated, and the sample is xanthochromic.
5. **C.** MRI is the best imaging technique for exploring soft tissue lesions such as in the spinal cord. The details of the examination (ie, bilateral leg weakness, difficulty urinating, and numbness from the waist down) pinpoint a lesion in the spinal cord rather than the head. See section “Diagnosing Neurologic Anatomic Abnormalities” for a full discussion.
6. **B.** Developmental milestones are an important component of the pediatric neurologic history (see section “Signs and Symptoms of Neurologic Disorders”). The other items are not components of the history.
7. **A.** Questions to evaluate symptoms should include ameliorating and exacerbating factors. See section “Signs and Symptoms of Neurologic Disorders” and Table e72-1 for additional items to ask.
8. **B.** Space-occupying lesions in the brain, papilledema, and coagulopathies are contraindications or relative contraindications to lumbar puncture. See section “Laboratory Findings for Neurological Disorders and Their Interpretation” for more information.
9. **A.** A comparison of these CSF results to Table e72-3 demonstrates values consistent with bacterial meningitis. White blood cells are elevated, protein is elevated, and glucose is decreased.
10. **D.** As seen in Table e72-2, cranial nerve examination is often abnormal in patients with myasthenia gravis.
11. **C.** Upper and lower motor neuron dysfunction seen in ALS often leads to cranial nerve dysfunction, reflex changes, and muscle weakness as seen in Table e72-2.
12. **C.** Therapy for Parkinson’s disease should improve motor function parameters such as tremor, bradykinesia, rigidity, and postural instability as seen in Table e72-2.
13. **D.** Cerebellar testing typically involves such tests as finger-to-nose, heel-to-shin, and rapid alternating movements as seen in Table e72-2.
14. **D.** Elements of the gait examination include walking (tandem, on heels, on toes), standing (Romberg test—closing eyes tests proprioception) as seen in Table e72-2 and may also include running and climbing.
15. **A.** Only conventional dye angiography images the small vessels adequately. See section “Diagnosing Neurologic Anatomic Abnormalities” for the advantages and disadvantages of this technique.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter e81: Evaluation of Psychiatric Illness

Mark E. Schneiderhan; Leigh Anne Nelson; Jeffrey R. Bishop; Steven Bauer

KEY CONCEPTS

KEY CONCEPTS

① Patients with psychiatric conditions are treated in all healthcare settings. All clinicians should apply the basic principles of the psychiatric assessment to provide the best care.

② The *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (*DSM-5*) and the Pocket Guide to the *DSM-5 Diagnostic Exam* provides clinicians with a standardized approach for the initial assessment and follow-up of patients with psychiatric conditions.

③ The World Health Organization’s International Classification of Diseases and Related Health Problems (ICD) classification is currently used in all patient care settings for billing purposes.

④ Clinicians should be prepared to gather both psychiatric and physical health histories from their patients. Obtaining a release of information (ROI) from patients to communicate with other healthcare providers or significant others is often necessary when sharing protected health information (PHI).

⑤ Patient interviews should be conducted in an atmosphere that ensures the comfort and privacy of both the patient and the clinician. Effective listening skills and the application of open-ended questions are essential in the interview process and for building a therapeutic relationship. Motivational interviewing can empower patients to participate and help design achievable treatment goals.

⑥ If a patient is in crisis, the clinician may feel some apprehension about asking certain assessment questions. Knowing what specific questions to ask can help facilitate inquiry about sensitive areas, such as delusional thinking and suicidality.

⑦ Current and past medication histories, including allergies, adverse effects, and clinical response are cornerstones of effective medication management. The medication history should be assessed for safety (eg, contraindications and medication interactions), tolerability (eg, adverse effects), efficacy (eg, response of target symptoms and adequate dosage and duration), and adherence (eg, affordability and the ability to take medications as prescribed).

⑧ Baseline mental status examination (MSE), psychiatric rating scales, and psychological/neuropsychological tests are useful tools in diagnosing and monitoring the severity of symptoms and response to treatments of psychiatric disorders.

⑨ Although there are no diagnostic tests for psychiatric disorders, physical and laboratory assessments can help rule out substances, medications, or medical conditions that may produce similar or overlapping symptoms.

⑩ Psychiatric rating scales, cognitive testing, and psychological testing provide objective measures of psychiatric symptoms, adverse effects, memory, and intellectual capacity and are often used in research and clinical settings.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the following videos to learn about the mental status examination (MSE) and build your knowledge of the MSE which is an assessment commonly used in psychiatry. The "Objective" component of the S.O.A.P. acronym S (Subjective), O (Objective), A (Assessment), and P (Plan) is used to describe the physical examination in the field of medicine. In contrast, psychiatry uses the MSE as the "Objective" component to describe the patient's appearance, concentration, thoughts, and feelings. Understanding the MSE can help you identify target symptoms for psychiatric pharmacotherapy. Try completing a practice MSE on a simulated patient.

> Psychiatric history and MSE tutorial: http://www.youtube.com/watch?v=U5KwDgWX8L8
>
> *(This video describes the MSE.)*
>
> Video demonstrating components of the MSE link: http://www.youtube.com/watch?v=1HbgPhq3MzA
>
> *(This video gives examples of the MSE and offers the opportunity to complete a practice MSE.)*

Self-evaluation questions:

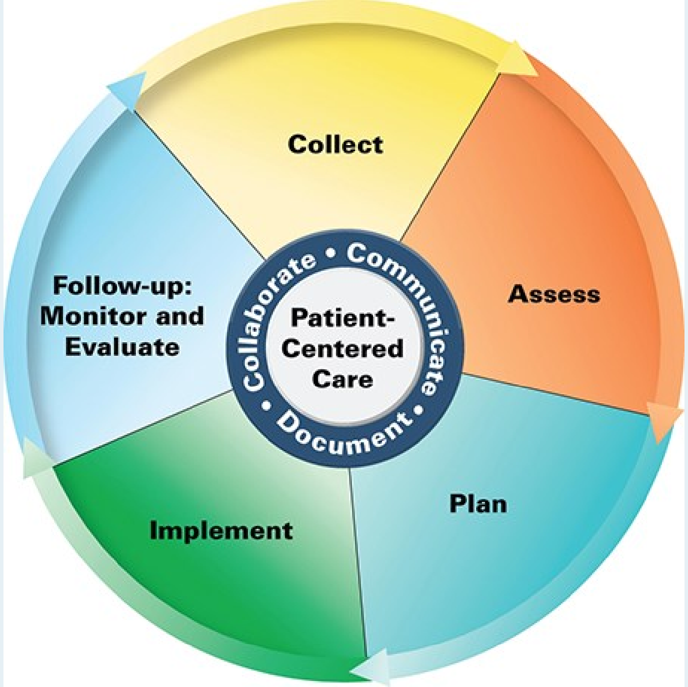
1. When would you administer a MSE? What type of information do you get from the MSE?
2. How would you use the information obtained from the MSE to care for a patient with psychiatric illness?
3. What is the difference between the MSE and the mini-mental state examination (MMSE)?

INTRODUCTION

① Common psychiatric conditions such as depression, anxiety, and substance use disorders are known to negatively impact overall treatment outcomes for chronic medical conditions and subsequently increase healthcare costs.[1] Patients with severe and persistent psychiatric conditions (eg, schizophrenia) often have untreated comorbid medical illnesses requiring care coordination between providers to address and prevent serious medical and/or medication-related consequences.[2,3] Additionally, many high-risk, rural, and underserved populations may not have easy access to fully integrated behavioral health and primary care services, which complicates treatment.[4,5] Furthermore, primary care providers may lack training to manage populations with health disparities.[4,5] New practitioners need to be aware of commonly occurring and sometimes comorbid psychiatric-medical conditions along with evidence-based solutions to achieve positive outcome for all patients.

PATIENT CARE PROCESS

Patient Care Process for the Psychiatric Assessment



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Current medications including over-the-counter (OTC), aspirin/nonsteroidal anti-inflammatory drugs, herbal products, and dietary supplements
- Past medication history, including medications not tolerated and any allergies to medications
- Current and past medical/psychiatric history (personal and family)
- Social history (eg, tobacco, cannabis, ethanol use) and dietary habits
- Overall functional status (see Table e81-1)
- Objective data
  - Mental Status Examination (eg, cognitive and emotional status) (Table e81-2)
  - Psychiatric rating scales, psychological tests, and suicide assessment (seeTable e81-2–81-5 and 81-7)[6,7]
  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), weight, height, body mass index (BMI)
  - Labs including glucose, lipids, complete blood count (CBC), serum medication levels, and pharmacogenetic testing results if available.

Assess

- Cognitive and emotional status (eg, MSE and presence of anxiety, depression (Table e81-2)
- Vitals: (eg, systolic/diastolic blood pressures, heart rate, and weight [BMI])
- Presence of medical conditions that may overlap psychiatric conditions or medication adverse reactions (eg, pain, nausea, vomiting, constipation, edema, tremors, headaches, dizziness)

- Presence of stress or possible stressors (eg, suicidality, recent surgery, pregnancy, estrogen use, recent hospitalizations, social determinants of health)
- Ability/willingness to seek additional psychiatric support (eg, psychotherapy, outpatient groups, hospitalization, community support groups, and so on)
- Ability/willingness to follow up with psychiatry services including medication management, psychotherapy, and/or substance use disorder treatment if indicated, and primary care around medical conditions
- Prior medication adherence
- Pharmacogenomics testing results

Plan*

- Medication therapy regimen including specific psychiatric medication(s), dose, route, frequency, and duration
- Monitoring parameters including efficacy (eg, serum medication monitoring, pain assessment, and safety plan [eg, calling 911])
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, medication-specific information, medication administration/adherence techniques, and review results of laboratory/pharmacogenetic test results)
- Patient education around self-monitoring for resolution of mental health symptoms, when to call the clinic with questions and concerns, and when to seek emergency medical attention (eg, suicidality)
- Obtain release of information to obtain collateral information (eg, family members, case managers, therapists, medical providers)
- Send letters and/or copies of progress notes to healthcare clinicians who are also providing medications or other therapies when appropriate (eg, starting new medications, concerns about possible adverse effects)
- Make referrals to other providers when appropriate (eg, psychologist, social worker, neurologist, pain specialist, dietician, and substance use disorder treatment)

Implement

- Provide verbal and written patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up to monitor and assess medication effectiveness (eg, clinical rating scales (see Tables e81-2–81-5 serum medication levels), adherence assessment of all recommendations
- Collaborate with patient, caregivers, and other healthcare professionals

Follow-Up: Monitor and Evaluate

- Resolution of behavioral health symptoms (eg, utilizing rating scales at every patient care encounter) (Table e81-2)
- Presence of adverse medication reactions (Table e81-2) and changing medical condition status
- Patient adherence to treatment plan using multiple sources of information (eg, medication refill records, medication administration records, serum medication levels)
- Reevaluate treatment plan at least every 1 to 3 months. Consider scheduling early (2 weeks) or more frequent follow-up visits after starting new medication therapy or monitoring behavioral risks such as suicidality

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

In the United State, depression, diabetes and substance use disorders are among the top 10 health burdens, defined by the total number of years of life lost and years lived with disability (ie, disability adjusted life-years). Between 1990 and 2016, the rates of depression (ranked 9th) increased by 27% and both diabetes (ranked 4th) and substance use disorder (ranked 7th) increased by 76% and 75%, respectively.[8] Of grave concern, the Centers for Disease Control and Prevention (CDC) recently reported escalating occurrence of fatal suicides; especially, among US citizens (54%) *not diagnosed* with a psychiatric condition.[9] Primary care providers may be unaware that their patient is considering suicide. Data show that 80% of fatal suicides occurred within 1 year after being seen by a primary care provider, and 44% occured within 1 month.[10] These rates are even higher in a subgroup of adults over the age of 50 years (97%) and females (89%) 1 year after being seen by a primary care provider. An earlier study of 5,894 patients who died by suicide found that approximately 22% of suicide-related deaths occurred within 1 week of an encounter with a primary care provider.[11] Integration of behavioral health services in primary healthcare settings may address the increasing health burden of psychiatric illness, co-occurring chronic illnesses (eg, depression and diabetes), reduced life-span, and collaborative reimbursement mechanisms for healthcare providers.[1] Reducing the barrier to mental health screening and treatment is important to help reduce currently seen mental health treatment disparites as high levels of mental distress can be seen at the intersections of gender identity, race, and ethnicity.[12,13]

Providing a fully integrated and unified care-coordination between psychiatric and primary care services improves treatment outcomes and provides cost-savings in general practice settings.[14–17] In response to evidence supporting unified care-coordination, the Centers for Medicare & Medicaid Services (www.CMS.gov) recently updated Medicare Part B Current Procedural Terminology billing codes to report behavioral health integration (BHI) services for beneficiaries.[18] Unlike traditional billing structures, a wide range of practitioners, including nonprescribers, can provide cost-shared BHI services focused on systematic care management of patients with psychiatric conditions.[18] Expectantly, BHI services will provide the infrastructure needed to achieve the Institute for Healthcare Improvement "Triple Aim" of improving the patient's experience of care, improve health and life-span of populations, and reduce cost of healthcare.[19]

Prioritization of advanced mental health training for all practitioners (eg, psychiatric, substance use, and suicide assessments) combined with unified behavioral and primary healthcare coordination will increase the likelihood of achieving optimal treatment outcomes.[1–5,8,11,17,20] This chapter provides an introduction to basic components of the psychiatric assessment, including diagnostic framework, interview strategies, utilization of laboratory data, validated assessment tools, and procedures used by clinicians to develop individualized treatment plans with patients. Greater information regarding neurologic assessments as well as the diagnosis of substance use disorders is contained in Chapters e72, "Evaluation of Neurological Illness" and e84, "Introduction to Substance Use Disorders." Readers needing a greater knowledge depth in areas such as diagnosis of psychiatric illnesses, motivational interviewing, and suicide assessment, are encouraged to explore other resources.[20–26]

OVERVIEW OF DIAGNOSTIC CLASSIFICATION SYSTEMS USED IN PSYCHIATRY

② The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) is the most widely accepted diagnostic reference in the United States for the care of individuals with mental disorders. The *DSM-5* provides a common language for practitioners to describe and diagnose psychiatric disorders, which is essential because there is considerable overlap of symptoms across many diagnoses.

③ In contrast, the World Health Organization's *International Classification of Disease and Related Health Problems (ICD)* primary function was to provide scientists a means of collecting all disease and health information across populations.[27] The ICD classification is currently used in both behavioral health and nonbehavioral health settings for billing purposes in the United States.

The current *DSM* version (*DSM-5*) organizes diagnostic categories as well as specific diagnoses using a developmental life span approach.[28] Diagnostic specifiers allow the clinician to clarify diagnoses, such as major depressive disorder, with terms to describe severity (eg, mild, moderate, or severe), course (eg, single episode, recurrent episode), and pattern of presentation (eg, with psychotic features). The *DSM-5* provides clinician resources such as objective diagnostic and follow-up assessments, utilization of severity rating scales, screening tools, and cultural assessments. For example, the *WHO Disability Assessment Schedule 2.0* (WHODAS) can be used to indicate the level of functional impairment (Table e81-1).[29] A complete list of the suggested patient assessment measures is available online (ie, "Online Assessment Measures").[6,25]

TABLE e81-1

Global Illness and Disability Assessment Scales

Rating Scale	Type	Scoring	Comments
Clinical Global Impressions (CGI) Scale CGI (S): Severity of Illness CGI (I): Global Improvement CGI: Efficacy Index	Clinician rated	1-item, CGI-S and CGI-I with a 7-point symptom severity and improvement score. 1-item CGI efficacy index: Total score: 1-4 marked improvement; 5-8 moderate; 9-12 minimal; 13-16 unchanged or worse	Observational and nonsymptom-specific for assessing three global subsets: severity of illness, global improvement, and efficacy index measures both therapeutic and adverse effects. CGI rating scales example can be found at: http://www.psywellness.com.sg/docs/CGI.pdf
WHO Disability Assessment Schedule WHODAS 2.0	Patient, proxy, or clinician (interviewer) rated	Assessment options include: 12 items, 12 + 24 items, and 36 items; total score is the summative score. Complex scoring "item-response theory." Uses an algorithm to determine a range of disability 0 = no disability and 100 = full disability	Covers six domains of functioning including: cognition, mobility, self-care, getting along, life activities, and participation.

Data from References 6,29–31.

The 5th edition of the *DSM-5* has retained the descriptive approach found in earlier editions with updates to the exact content. This descriptive text provides information for all mental health disorders regarding diagnostic features, prevalence, development and course, risk and prognostic factors, functional consequences of the disorder, differential diagnosis, comorbidity and, where applicable, culture- and gender-related diagnostic considerations.

Diagnosing mental disorders and developing an appropriate treatment plan with patients requires the clinician to engage in a comprehensive interview that assesses the patient's presenting problem(s), and provides the biopsychosocial context for understanding those problems. *The Pocket Guide to the DSM-5 Diagnostic Exam* includes examples of screening and follow-up questions used in a diagnostic interview for each of the mental disorder categories in *DSM-5*.[32] It also discusses approaches to establishing a therapeutic alliance with patients, conducting a 30-minute diagnostic interview, a stepwise approach to differential diagnosis, and evaluations in special populations (ie, cultural assessments).

Currently, *DSM-5*, WHO ICD-10, and recently released ICD-11 will continue to exist as companions in the diagnostic coding classification of psychiatric disorders. In the United States, the ICD, as it is used in reference to psychiatric disorders, is mandated by insurance companies to secure payments; whereas globally it is used to secure information regarding the epidemiology of the disorders. Broad differences currently exist between *DSM-5* and ICD-10. However, ICD-11, that has an implementation start date scheduled for January 1, 2022, appears to be more in line, at least organizationally, with *DSM-5*.[27] It will be important during these transitions to understand both systems and be fluent with integration.

In summary, the *DSM-5* and ICD provide clinicians with a systematic approach toward evaluating patients, thereby allowing for the development and implementation of better treatment plans and a more consistent way to evaluate treatment outcomes.

THE CLINICAL INTERVIEW

The psychiatric clinical assessment is more than a verbal communication exchange with the patient, as the clinician should be prepared to assess both the psychiatric and physical health conditions of patients. Often multiple prescribers are involved in the treatment of patients that can result in the occurrence of polypharmacy. Communication exchanges between psychiatry and primary care services are often fragmented, even if they are co-located, due to varying degrees of practice integration and siloes of practices.[1,33,34] Training of clinicians to recognize effects of social determinants of health such as lack of nearby health services, unmet basic needs (eg, affordable housing, healthy food), economic inequities (eg, education, employment), and social (eg, relationships, isolation) disparities can reduce barriers and increase access to care.[4,5,35,36] Clinician recognition and assessment of the effects of stigma and discrimination during clinical interviews can reduce impacts of violence and suicide in vulnerable racial, ethnic, and sexual minorities and adolescents.[34,37] Also, clinician awareness that patients with severe and persistent mental illness (SPMI) have a shortened life span compared with patients without psychiatric disorders increases the urgency for ensuring continued access to primary care services.[38] For example, routine laboratory monitoring is critical since a significant number of patients who take antipsychotic medications are not adequately monitored for adverse medication effects, such as emergent diabetes and dyslipidemia.[39–43] Therefore, the interviewer should be aware of the significant barriers to care in this population to ensure the patient is receiving consistent and high-quality management of co-occurring conditions.[1–5,16,17,34–36,38,39,41]

Release of Information

④ Because coordination of care is often lacking, permission from the patient should be obtained before the interview is completed to obtain “collateral information,” such as psychiatric and medical diagnoses, laboratory test results, medication lists, and other verbal or written records. Collateral information can be obtained by asking the patient to sign a “Release of Information” (ROI), which is mandatory in order to contact significant others, family members, and other clinicians.[44]

In summary, the clinician should be prepared to assess the psychiatric and physical health of the patient, which is discussed in more detail in the “Mental Status Examination” and “Physical Examination and Laboratory Assessment” sections later in this chapter.

Interview Techniques

⑤ Interviews should be conducted in a quiet, nonstimulating, private, and comfortable area where the patient and the interviewer feel at ease.[21,22,32,45] The interview setting should be appropriate to the patient’s level of acuity and a safe environment for both parties. The interviewer should introduce themselves, explain the purpose of the meeting, and ask about the reasons or expectations for the visit in order to establish a trusting relationship (ie, therapeutic alliance). Additionally, the interviewer should confirm the patients preferred gender pronouns and use them consistently, being careful not to make assumptions. Generally, open-ended questions come first followed by questions focused on more specific or personal data. Open-ended questions allow the patient to provide descriptions and other information in his or her own words. Even though more specific questions may then be necessary to fill in the gaps, beginning in this manner minimizes the risk of “leading” the patient. For example patients can respond to specific questions and “yes” or “no” questions with answers they think the interviewer wants to hear. The interviewer must listen carefully and remain nonjudgmental about the information offered by the patient to develop trust and rapport and to ensure completeness and accuracy of the information. Motivational interviewing is another technique that can be useful for engaging the patient if conflicting issues arise such as discussions around medication adherence, tobacco, substance, or alcohol use.[46] The motivational interview approach to patient interactions is described by the acronym OARS (*O*pen-ended questions, *A*ffirmations, *R*eflective *L*istening, and *S*ummary).[46] More comprehensive descriptions and training opportunities for motivational interviewing are available in other sources.[47,48]

Whether a clinician takes notes or just listens during the interview is an individual decision; the primary considerations are accurately recalling the details of the examination and assuring that the patient is comfortable with the note taking. Table e81-2 provides examples of questions useful for gathering information toward the completion of the clinical interview. Before any conclusions are made during a patient interview, the impact of social determinants of health, such as trauma history, safety, housing needs, food insecurity, and financial status needs to be assessed.[49] Ethnicity and cultural background can influence a patient’s presentation and clinical assessment. For example, a spiritual belief or fear can sound delusional in one culture but may be a standard belief in another culture. If a clinician is unclear whether culture of origin accounts for some of the patient’s symptoms, he or she should obtain an ROI to consult with a family member or person familiar with the patient’s culture of origin.[50] The Cultural Formulation Interview found in the assessment tools of *DSM-5* can also be used to assist the clinician who suspects that cultural influences may be affecting the diagnostic assessment.[6]

TABLE e81-2

Examples of Interview Questions for Assessing Psychiatric Disorders[a]

Mania

1. Tell me what your typical day is like.[b]
2. Do your thoughts go faster than you can say them?
3. Have you noticed a change in the amount of sleep that you require?
4. Have you spent a lot of money lately, and what did you spend it on?
5. Do you have a lot of extra energy? (To assess hallucinations and delusions, see "Schizophrenia" section below.)

Depression

1. How do you spend your time?[b]
2. Do you cry without any reason?
3. Do you still enjoy the same hobbies or activities that you once did?
4. Has your weight changed recently?
5. Have you had changes in your energy level recently?
6. Do you have any guilty feelings?
7. Do you find it difficult to remember phone numbers, names of friends, appointments, and so on? (To assess sleep and suicidal potential, see "Sleep" and "Suicide" sections below.)

Schizophrenia

Delusions

1. How do people treat you?
2. Do you feel that people plot against you?
3. Do you ever feel that you are watched or spied on?
4. Do you have any special abilities?
5. Does anyone ever try to mess with you or bother you?
6. Do others read your thoughts?

Hallucinations

1. Does the TV or radio ever tell you things?
2. Do you hear voices that other people don't hear?
3. What do they say? How many voices?
4. How often do they bother you?
5. Do the voices ever tell you to kill yourself or someone else?
6. Have you ever heard your name called when there is no one?
7. Have you ever seen anything strange that you can't explain?
8. Do you ever see things that bother you and no one else?
9. Do you want to act on what the voices say?

Thought Broadcasting or Insertion

1. If I stood by you, could I hear your thoughts?
2. Does your head ever act like a radio?
3. Do you feel that others can put thoughts in your head?

Insight

1. What reasons did your family give you for coming here?
2. What concerns brought you here?[b]
3. Do you consider yourself in need of help?
4. What does your medication do for you?[b]

Sleep

1. Tell me about your sleep.
2. How many hours do you sleep each night at present?
3. How many hours do you usually sleep at night?
4. Do you sleep all through the night?
5. Is there a reason for your waking up?
6. Do you have trouble falling asleep?
7. How do you feel when you wake up?

Suicide Screening[30]

1. Have you wished you were dead or wished you could go to sleep and not wake up?
2. Have you had any actual thoughts of killing yourself?
3. Have you been thinking about how you might kill yourself?
4. Have you had these thoughts and had some intention of acting on them?
5. Have you started to work out or worked out the details of how to kill yourself? Do you intend to carry out this plan?
6. Have you ever done anything, started to do anything, or prepared to do anything to end your life?

[a] For all of these example questions, try to get the patient to expand on their answers.

[b] These assessment questions or inquiries may be used early in the interview to assess other psychiatric disorders as well.

Interviewer Challenges

⑥ Patient assessments can be challenging when symptoms of the condition prevent effective engagement with the clinician. While patients with mania may exhibit speech that is rapid and unorganized, patients with depression may respond with few words. Patients in the manic phases of bipolar disorder may not pause as they speak (ie, pressured speech), making it difficult for the interviewer to interject. In these cases, the interviewer can regain control by politely redirecting the patient back toward the question.

The interviewer should always be prepared to adjust their communication approach based on the responses or reactions of the patient. Often, as in the disease of schizophrenia, a patient may demonstrate *poor* insight and judgment. It can be common for the clinician to react negatively with anger if the patient seems to be manipulating and not adherent with treatment. Instead of reacting negatively, one principle in motivational interviewing is to “roll with resistance” in which the clinician accepts the patient’s perspective and encourages the patient to explore their own solutions.[21,46] In another situation, patients with psychosis may be paranoid and appear guarded or frightened by the interviewer’s empathetic or even supportive statements, or questions.[51] During any patient encounter, clinicians should be aware of strong emotions such as fear, anger, or frustration and be careful not to judge or react to the patient. Overall, the best approach when feeling tension during the patient encounter is to remain calm, speak softly, be respectful, use shorter or closed-ended questions, and be “matter of fact” for asking for only essential information.[21] Sometimes patients can become agitated and in rare situations, violent. Often violence is preceded by increased psychomotor agitation as evidenced by pacing, shaking, speaking in a loud voice, crossing arms, or gripping an object (ie, chair or table). In the rare instances where there may be a concern about safety, the interviewer should remain at a safe distance from the patient and avoid any behavior that could be misconstrued as threatening, such as being overly friendly (eg, touching) or unnecessary staring. In these circumstances, it is best to keep the encounter brief and interview the patient in the presence of another healthcare provider. Both the patient and interviewer should have equal access to leave the room if either becomes too uncomfortable. If a patient becomes threatening to the interviewer, the interviewer should not hesitate to leave the room and call for help. In summary, applying motivational interviewing skills or just remaining calm, quiet, and respectful may de-escalate the agitated patient, preserve the therapeutic alliance, and improve overall treatment adherence.[46–48]

Risk Assessment and Suicide

The risk assessment requires that the interviewer be knowledgeable and comfortable discussing dangerous behaviors such as aggression and suicidality. The interviewer must regularly, at each patient visit, assess risk factors and document the patient's level of suicidality or harm to others. The clinician needs to be aware of risk and protective factors associated with suicide and patient's recent past history to predict current suicide risk at the time of the patient encounter.[52,53] However, readers must be aware that often patients may withhold specific information about recent risky behaviors and simply screening for suicide may not always elicit dangerous intent (eg, injury to self or others).[20] A person is most likely to withhold information if they feel embarrassed, fear discovery, and/or fear their suicide plans may be interrupted. Patients can sense an interviewer's lack of comfort and anxiety discussing this topic and be reluctant to discuss suicidal thoughts and risk. To address this tendency to withhold information, experts recommend an interview approach known as the Chronological Assessment of Suicidal Events.[20] The Chronological Assessment of Suicidal Events approach can aid the clinician in establishing mutual trust and empathic rapport with the patient to determine recent or imminent lethal or dangerous behaviors (eg, suicide attempt).[20] An interviewer should not use technical words like "suicide" and instead ask directly "Have you had any thoughts about killing yourself?" Asking a patient about dangerous thoughts, intents, or plans will not increase the risk.[20] The risk is greater if these questions are never asked or signs of distress (eg, psychosis, psychological pain, incurable health condition, recent loss) are ignored.[53] Patients experiencing command auditory hallucinations with violent content, and/or current substance/alcohol use, and/or recent history of aggression to self or others may require immediate attention and even hospitalization. In summary, with advanced education, supervised experiential training, and clinical experience assessing behavioral risk, a clinician may save their patient's life or prevent harm to another person. Please note that this section is only meant to serve as an introduction to the risk assessment. Readers are encouraged to explore other resources and training opportunities on suicide assessment.[20,54–58]

Psychiatric History

History of psychiatric disorders in patients and their families provides important information when formulating a diagnosis and treatment plan. Information collected should include the current and previous psychiatric diagnoses, psychiatric hospitalization and emergency room visits, reasons for admission (ie, suicide intentions), clinical presentation of acute symptoms, time frame between acute episodes, level of functioning between episodes, length of each episode, total duration of the psychiatric disorder, and treatment given during each episode, as well as response to those treatments.[21] Baseline functioning or the highest level of functioning achieved in the last few years is important because it helps to define a treatment goal. Information on the history of the current episode and reasons for presenting to the clinician should also be gathered. A family history should include a medication history of the immediate relatives because a family member's response to a given medication might predict an individual patient's response to that same medication.[21]

Social History

A social history contains educational and occupational background; religion; marital status; substance use, including tobacco, cannabis, caffeine, and alcohol; and current living situation. By understanding a patient's living environment and social determinants of health, strategies to foster treatment adherence, reduce stress, and increase social support can be developed. To probe this area initially, the clinician can ask patients to describe their social support network. This can be followed by more specific questions such as: "To whom are you closest?" or "In whom do you confide?"

Medication History

⑦ A thorough current and past medication history is one of the most important contributions a clinician can make to treatment planning. The history should include medications for both psychiatric and medical conditions and list all medications, including OTC and supplements, taken by the patient. The history should also report how each medication was tolerated and describe the responses to a single medication or combination of medications. All allergies must be noted. Because most psychiatric medications have a delayed onset of effect, it is important to determine whether an adequate trial (dose and duration) was provided before the patient is deemed “nonresponsive” to that medication. If a patient has a history of nonadherence, specific causes should be investigated. Causes of nonadherence may include, but are not limited to medication cost, complicated dosing schedules, lack of insight, failed efficacy, and adverse effects.

Mental Status Examination

8 The mental status examination (MSE) is a key patient assessment tool in psychiatry and is analogous to the physical examination in medicine. The MSE is completed through a direct patient interview and provides a systematic method of organizing and reporting current behaviors, thoughts, perceptions, and functioning. The MSE has several components (eg, appearance, attitude, activity, speech and language, mood and affect) and is combined with other aspects of the patient workup (history of present illness, physical examination, appropriate laboratory tests, and medical and psychiatric history) to give a full picture of the presenting problem and factors contributing to the mental disorder.[21–26,32,45] The addition of symptom rating scales incorporated into the MSE can greatly enhance the clinical assessment. Consistent identification and tracking of symptoms with rating scales can enable both the clinician and patient to mutually construct specific treatment goals and measure clinical progress such as changes in symptom frequency or severity over weeks or months.[30] Although terminologies can be misleading, the MSE should not be confused with the Mini-Mental State Examination (MMSE), which is discussed in the “Neuropsychiatric Rating Scales” section later. The components of the MSE include:

Appearance and Attitude Toward the Examiner

The appearance of the patient throughout the interview should be noted, including age, dress, grooming and hygiene, use of cosmetics, and facial expressions. A description of appearance also should include unusual physical characteristics (eg, mannerisms, restlessness, and so on) and the general state of physical health. The interviewer should note whether the patient is cooperative, mute, hostile, paranoid, guarded, and/or withdrawn.

Activity

Motor activity may be excessive or diminished. Overactivity during the interview can range from hand wringing; restless leg movements; and picking at clothing, skin, or hair to severe pacing in the room. Underactive patients move less than expected. Patients with rigid posture, an absence of movement, and failure to communicate may be catatonic or paranoid or experiencing medication adverse reactions.

Speech and Language

The quantity, flow, and speed of speech and the amount of eye contact should be noted. The appropriateness and degree of eye contact varies significantly among cultures, and before poor eye contact is interpreted, the patient’s cultural background should be considered. Speech should be assessed as to whether it proceeds logically in a goal-directed manner or whether the content is vague and poorly organized. Abnormal speech characteristics include thought blocking, whereby the person suddenly stops speaking without any obvious reason. *Thought blocking* usually occurs when hallucinations or delusions intrude into the person’s thinking or when upsetting issues are discussed. Conversely, *pressured speech* is observed in conditions such as bipolar disorder. *Flight of ideas* is overproductive, rapid speech during which the patient jumps rapidly from one idea to the next. *Circumstantial* and *tangential speeches* are evidence of disorganized thoughts. *Circumstantial speech*, whether pressured or not, lacks a clear direction because of excessive unrelated information, but the circumstantial patient eventually makes full “circle” back to their point. In tangential speech, however, the ultimate point is never made. *Perseveration* is repetition of an original answer to subsequent questions. *Mutism* is identified when the patient does not respond even though they are aware of the discussion.

Affect and Mood

Affect describes the patient’s current emotional tone, as expressed through facial expression, body posture, and tone of voice, all of which can be objectively observed by the clinician. Mood describes feelings, which are subjectively reported by the patient. Changes in facial expression and the presence of tears, flushing, sweating, or tremors should be noted. Affect can be described further by its range, appropriateness, intensity, and stability. For example, in individuals with schizophrenia or depression, the affect can be *flat*, whereby no change in expression occurs throughout the interview. In contrast, during a manic episode, the affect is very intense and often *excited*. *Blunted affect* denotes that the range of emotional expression is reduced but not absent. An example of *inappropriate* or *incongruent affect* is when a patient laughs in a situation that would be expected to produce sadness. A rapidly shifting affect from one extreme to the other is described as *labile*.

Thought and Perceptual Disturbances

A variety of thought disturbances can occur in psychiatric disorders. Many of these disturbances generally indicate the presence of psychosis, psychotic disoder (eg, scizophrenia), or impaired reality testing. *Delusions* are fixed, false beliefs that are not based in reality or consistent with the patient's religion or culture. Delusions can be paranoid, somatic, or grandiose in nature. Delusions are often unshakable, and although the clinician can challenge the delusional thinking, one should not attempt to talk to a patient out of a delusion. The lack of awareness of a psychiatric disorder (anosognosia) can often accompany delusions. *Thought broadcasting* is the belief that one's thoughts are audible to others. *Hallucinations* are false sensory impressions or perceptions that occur in the absence of an external stimulus. Hallucinations can be auditory, visual, olfactory, tactile, or gustatory and can be continuous or intermittent. In contrast, *illusions* are visual misperceptions involving a misinterpretation of a real sensory stimulus. For example, a person experiencing an illusion may react in fear if they momentarily misperceive a breeze moving a curtain to be an intruder. This phenomenon does not always indicate a psychiatric disorder and can be seen in persons without psychiatric disorders. Not all thought disturbances are indicative of psychosis. For example, the couplet of obsessions and compulsions can indicate the presence of obsessive-compulsive disorder, which is not considered to be a psychotic disorder. *Obsessions* are unwanted thoughts or ideas that intrude into a person's thinking. *Compulsions* are actions performed in response to the obsessions or to control anxiety associated with the obsession.

Evaluation of Cognition

The MSE assesses sensorium, attention, concentration, memory, and higher cognitive functions such as orientation and abstraction. If deficits in memory and concentration are primary or secondary complaints of the patient or these deficits are apparent during the interview, more formal or standardized mental status testing (eg, MMSE) may be required. The clinician should document whether the patient has received medications with sedative properties because the outcome of the examination can be altered if central nervous system depressants were recently taken.

Sensorium, or level of consciousness, refers to the alertness of the patient, and if they are not fully alert, the amount of stimulation needed to awaken the patient. Attention and concentration can be further assessed using serial subtraction by 7s ("serial 7s") or 3s or by having the patient spell a five-letter word backward (eg, d-l-r-o-w). General intelligence can be assessed casually by asking factual information about current news items, recent presidents, or popular television shows or sporting events. *Memory* is the ability to recall prior information and experiences. There are many descriptors referring to specific types of memory such as working memory (ie, the capacity to hold information such as a phone number in mind for a few seconds), short-term memory (ie, the ability to recall newly acquired information after several minutes), and long-term or remote memory (historical facts) that are commonly assessed as part of the MSE. Orientation to time, place, person, and situation assesses short-term memory. Asking a patient to recall three objects, 5 minutes after they are learned, is the definitive test for short-term memory. Although deficits in short-term memory may be seen in depression and anxiety, this finding is the hallmark feature of dementia. Asking the patient to do a certain task (eg, pick up a pen with his or her right hand and then fold a piece of paper and pass it to the examiner) or spelling a five-letter word in reverse are examples of testing working memory. Patients with cognitive deficits, such as those seen in dementia and schizophrenia, can exhibit deficits in working memory. Remote memory is assessed by asking patients to recall old facts about their lives, such as where they were born or where they went to school. Whereas remote memory usually remains intact the longest in patients with intellectual decline, the inability to create new memories is generally the first sign of a memory deficit. *Abstraction* is the ability to interpret information such as a proverb (eg, "People in glass houses shouldn't throw stones") or identify similarities or differences between words (eg, apple and orange). Abstraction is influenced by education, cultures, and linguistic fluency; thus, an inability to abstract is not always a sign of a psychiatric disorder. Persons with schizophrenia often provide *concrete* (literal or superficial interpretations) or *bizarre* responses to probes of abstraction.

Risk Assessment

Clinicians typically document the presence or absence of violent, suicidal, and/or homicidal thoughts in the mental status narrative or in a separate "risk assessment" section of the progress note. The risk assessment is typically comprised of core principles including motive/desire (ie, killing self or others, psychological pain, hopelessness, helplessness, perceived burden on others, feeling trapped or intolerably alone); capability (eg, history of nonfatal suicidal behavior, available lethal means of killing self/others); intent (eg, active suicidal behavior, plan(s), preparatory behaviors, expressed intent); and buffers/connectedness (protective factors) such as immediate supports, core values/beliefs, engagement with helper, ambivalence/fear, and sense of purpose.[53,58] Examples of suicide assessment questions are outlined in TABLE e81-2. The Columbia-Suicide Severity Rating Scale (C-SSRS), is an evidence-supported tool for suicide assessment consisting of a simple series of questions that can be adapted to a particular setting, population, and language (eg, Screener with Triage for Primary Care Settings).[55,56] Healthcare providers can use the C-SSRS to assess suicide risk and identify patients at increased risk of suicide.[56]

Insight and Judgment

Insight refers to patient awareness that they have a psychiatric disorder and the impact of that disorder on their life. *Anosognosia* is a term used to define the complete lack of insight or awareness of a psychiatric disorder. For example, the symptom of *poor* insight is thought to be the main cause of *poor* judgment such as nonadherence with prescribed medications.[57] Levels of insight may be variable based on the level of acuity of the psychiatric disorder.

Judgment is the ability to make decisions appropriate to the situation and can be impaired in people with a variety of psychiatric disorders. Judgment can be assessed by asking patients how they would handle either their current or a hypothetical situation. As with insight, judgment also can be fluid. For example, intoxicated patients can demonstrate *poor* insight and judgment only to improve over several hours as their blood alcohol concentration decreases.

In summary, the MSE is the clinician's observations and expert opinion based on the patient's history, verbal responses, nonverbal reactions, appearance, and behaviors. The MSE is primarily used to establish the patient's diagnosis, target symptoms, response, and treatment plan. In addition to the MSE and based on the discretion of the clinician, a physical examination, laboratory assessments, objective rating scales, and psychological testing may be needed for a comprehensive mental health assessment and follow-up. These assessment tools are described in the following sections.

PHYSICAL EXAMINATION AND LABORATORY ASSESSMENT

⑨ There is no consensus about specific laboratory tests for diagnosing or evaluating psychiatric disorders.[25] An emerging area of interest is the identification of biologic markers (eg, pharmacogenetics) as diagnostic tools, predictors, or indicators of medication response.[59] Recent developments in brain imaging (functional magnetic resonance imaging [fMRI]) using computer algorithms are being studied and show promise in diagnostics. For example, a recent meta-analysis of fMRI studies found evidence for diagnostic specificity in schizophrenia and bipolar disorder.[60] Although there are no diagnostic tests to definitively indicate that a patient has a specific psychiatric disorder, physical assessments and laboratory tests are important to clarify the etiology of presenting symptoms.

Physical Assessment

Patients who present with psychiatric symptoms need a careful medical assessment for overlapping symptoms from differing causes.[2,3,25,26,28] A complete physical examination, along with a detailed medical and medication history, vital signs, BMI, pregnancy test when indicated, and routine blood chemistry are commonly part of the workup of persons with a psychiatric disorder. In most cases, a physical examination should be chaperoned in the behavioral health setting.

Presenting symptoms can have multiple etiologies (ie, medical, medications, and psychiatric disorders). Medical conditions, psychiatric disorders, medication adverse reactions, and substance use can cause symptoms that are often indistinguishable. Patients with psychiatric disorders, especially depression and anxiety disorders, may present to primary care providers with only physical or somatic complaints (eg, gastrointestinal) and thus receive unnecessary medical treatment, while the root psychiatric cause is overlooked.

In contrast, psychiatric disorders may predispose a person to medical complications. For example, patients with SPMI have a high prevalence of modifiable risk factors such as poor nutrition, obesity, substance use disorders (eg, tobacco, alcohol, and other substances), and sedentary lifestyles, leading to increased morbidity and mortality.[1–5,8,9,16,17,38,41,49] Patients diagnosed with schizophrenia can have a 13 to 15 years of potential life lost with an average weighted life expectancy of 63 years compared to the general US life expectancy of 79 years based on 2018 data and 77 years based on 2020 data due to the Covid-19 pandemic.[61,62] The recent Covid-19 pandemic increased mortality rates by three-fold in patients diagnosed with schizophrenia, after adjusting for medical conditions.[63] Other possible causes leading to premature deaths in patients with schizophrenia may include suicide, tobacco use, substance use, and comorbid medical conditions, including cardiovascular disease, diabetes, respiratory disease (eg, chronic obstructive pulmonary diseases), and other infectious diseases (eg, influenza, pneumonia, and HIV/AIDS).[61]

Psychotropic medications, such as antipsychotic agents used for the treatment of mental illness can also cause or exacerbate medical conditions, such as diabetes mellitus, hyperlipidemia, or cardiac arrhythmias, necessitating an initial assessment and routine monitoring as recommended in treatment guidelines.[39–41,64,65] Baseline and follow-up assessments are needed to help document future adverse medication reactions. For example, the 2004 expert consensus guidelines recommend that patients taking antipsychotics should be periodically screened for symptoms of metabolic syndrome, including body weight, waist circumference, blood pressure, and fasting serum lipids and glucose.[41,64,65] Please refer to Chapter 87 "Schizophrenia" for in-depth information on antipsychotic adverse effects.

Abrupt onset of psychiatric symptoms can be an important clue that a medical cause (eg, delirium from an encephalopathy) may be present, whereas most chronic psychiatric disorders (eg, schizophrenia) may have a prodromal period prior to an acute episode. Patients older than 40 years at first presentation are more likely to have a medical cause for their psychiatric symptoms, because major psychiatric disorders, such as schizophrenia and bipolar disorder, usually first present in adolescence or early adulthood. Family history can provide additional clues. Patients with fluctuating levels of consciousness; disorientation; memory impairment; or visual, tactile, or olfactory hallucinations are more likely to have a medical basis for their presentation that can be diagnosed by medical diagnostics (eg, laboratory tests, computed tomography [CT], magnetic resonance imaging [MRI]).

Laboratory Assessment

General laboratory screenings are useful for medication monitoring and ruling out medical causes of psychiatric disorders. Urine toxicology and blood alcohol tests play an important role in identifying the contribution of alcohol and substances to the presenting symptoms. Additional testing can include an electroencephalogram (EEG) to evaluate for the presence of seizure activity and other neurologic conditions; CT or MRI scans to detect structural abnormalities; sedimentation rate and antinuclear antibodies for autoimmune disorders; vitamin B_{12} and folate concentrations for anemias; endocrine tests (eg, thyroid function) for identifying hormonal and metabolic disorders; and other workups as needed.[25] Laboratory tests should be individualized to the patient's age, medical/medication history, cooperativeness, and physical health. However, extensive testing is usually unnecessary and not cost-effective.

Clinicians also use diagnostic tests to evaluate appropriate medication use, such as pregnancy monitoring with divalproex, renal status when using lithium, or an electrocardiogram (ECG) when using medications that prolong the QT interval (eg, tricyclic antidepressants such as amitriptyline). Serum medication concentration monitoring is recommended for medications with a narrow therapeutic index (eg, lithium, divalproex, and carbamazepine). Serum concentration monitoring can also be useful for assessing medication adherence when there is an inadequate response or adverse medication effects. The clinician should differentiate "therapeutic range," the serum concentration to target for beneficial effect, from "reference range." Discretion is necessary since most laboratories provide a "reference range" for many medications which reflect serum concentration variability among patients taking a specific medication. Therefore, serum medication concentration reference ranges may not always predict therapeutic benefit or adverse medication effects. Consensus guidelines are available to help guide clinicians' interpretation of serum medication concentrations.[66] Finally, clinicians must also be aware of pharmacokinetic and pharmacodynamic medication, food, and genetic interactions that occur with, which raise the probability of adverse effects, toxicity, or loss of efficacy.

Pharmacogenetics may help clinicians predict and minimize medication and disease interaction risks and adverse medication reactions. Presently there are 40 medications of potential relevance for psychiatric disorders that have pharmacogenetic biomarker information referenced in the US Food and Drug Administration (FDA) product labeling (drugs@FDA). Much of this information highlights the potential influence of genetically determined metabolizer status on dose requirements or dose-related outcomes, but does not provide recommendations about whether or not to obtain pharmacogenetic testing. The newly established FDA Table of Pharmacogenetic Associations further categorizes drug–gene relationships into three sections: Section 1: Pharmacogenetic Associations for which the Data Support Therapeutic Management Recommendations; Section 2: Pharmacogenetic Associations for which the Data Indicate a Potential Impact on Safety or Response; and Section 3: Pharmacogenetic Associations for which the Data Demonstrate a Potential Impact on Pharmacokinetic Properties Only.[67] A growing number of commercial pharmacogenetic tests are now available that assess genes related to neuropsychiatric medications and provide clinical decision support to prescribers.[68] Complicating matters, commercial pharmacogenetic tests assess a number of genes that go beyond those listed in FDA product labeling. Additionally, the interpretation of genotype results and decision support provided back to prescribers can differ across commercial tests that use a "combinatorial" approach to collate results from pharmacokinetic and pharmacodynamic genes.[69] To assist prescribers, consensus guideline development groups have published resources to facilitate the interpretation of genetic test information.[70–73] As it relates to medications used to treat psychiatric conditions, the current evidence suggests potential utility of genes that influence medication metabolism in relation to dosing and dose-related outcomes for some but not all antidepressant and antipsychotic medications.[74] Additionally, genetic variation in immune system genes may predispose some individuals to life-threatening reactions such as Stevens–Johnson syndrome if exposed to carbamazepine and other antiseizure medications (see Chapter 75, "Epilepsy").[75] Prior to ordering a pharmacogenetic test, it is recommended that the patient be counseled on the reasons for the test, and clarifying what the patient should expect and not expect from the results.[76] Presently, insurance reimbursement for pharmacogenetic tests is highly variable. Thus, prior to ordering a test, financial considerations should be discussed with the patient. In striving toward patient centered care, clinicians are encouraged to become knowledgeable about pharmacogenetic testing to address patient questions, encourage conversation, and shared decision making around medication selection.

In summary, a range of assessments and laboratory tests can aid clinicians in conducting comprehensive workups to verify diagnoses, identify overlapping medical or potential medication-related problems, and optimize the patient's medication experience.

MEASUREMENTS OF PSYCHIATRIC SYMPTOMS AND COGNITIVE FUNCTION

⑩ In addition to the MSE, symptom-based rating scales are useful tools to provide an objective way to measure subjective data (eg, feelings, thoughts, and perceptions) and to screen or diagnose specific disorders. Because there are many types of scales from which to choose, the clinician rater needs training and experience to select and effectively use the most appropriate scale. Rating scales are used in a variety of settings, including research and patient care, and can serve an administrative purpose, such as quality control.[30]

Some rating scales are self-administered ("patient-rated") and do not require a staff member to collect the data. Patient-rated scales require minimal resources to administer and can provide valuable information. However, some patients may be unable to complete a rating scale for a variety of reasons, including limited literacy, instrument length (ie, number of items), and severity of symptoms.

In contrast, "clinician-rated" scales may provide a more consistent measure of target symptoms or behaviors. However, major drawbacks includes the substantial time commitment for staff learning how to administer the tests, variabililty of symptoms interpretation among clincians, and the inability of some patients to tolerate these interviews, especially patients who are severely paranoid or agitated. For optimal benefit, repeated use of rating scales are usually necessary to objectively describe longitudinal changes over a defined treatment period as opposed to a single snapshot of a complex clinical situation.

Sensitivity, specificity, reliability, and validity are important considerations when selecting a rating scale. *Sensitivity* refers to a test's ability to detect a symptom or illness given that the symptom or illness is present. *Specificity* refers to a test's ability to correctly determine that a symptom or illness is absent when the person does not have the illness.[30,77]

Reliability is the extent to which the score on the scale reflects the hypothetical "true" score and how much interference occurs from outside influences.[30,78] Reliability is reported by the correlation coefficient, which represents a chance correlation (0.00) or perfect correlation (1.00). Rating scales with correlation coefficients of less than 0.7 are usually considered unreliable for clinical studies. *Interrater reliability*—agreement in rating scores among clinician raters—is important to achieve when multiple clinicians rate the same patient or population. Interrater reliability is established by having all raters independently rate individual patients at the same time to determine the correlation of their scores.

Validity, in contrast, is the ability of a scale to measure what it was designed to measure. Various validity tests are performed on a rating scale to ensure that the scale assesses the appropriate aspects of the illness (*content validity*), the correlation with diagnoses or clinical change (*criterion-related validity*), and the extent to which the scale measures symptom traits in contrast to a specific symptom (*construct validity*).[30,78] Before administering any rating scale, the clinician should be trained or observed using the rating scale and have thorough knowledge of the rating scale's strengths and limitations.

Psychiatric Rating Scales

Psychiatric rating scales provide the clinician, patient, and researcher with quantitative measures of symptoms associated with many psychiatric disorders and medication-related adverse effects. Symptom-based rating scales for specific illnesses such as schizophrenia (Table e81-3), depressive and bipolar disorders (Table e81-4), anxiety, stress/trauma-related, and obsessive compulsive disorders (Table e81-5) and neurodevelopmental disorders (Table e81-6) can be used to complement the initial diagnostic formulation, help screen for new symptoms, and monitor symptom severity at each follow-up visit. In addition, clinician and patient rating scales can be used to guide questions asked during the patient care interview, articulate patient-centered goals of therapy, aid in treatment planning, and assessing ongoing quality outcome of patient care.

TABLE e81-3

Schizophrenia Rating Scales

Rating Scale	Type	Scoring	Comments
Brief Psychiatric Rating Scale-Anchored (BPRS-A)	Clinician rated	18-item, 7-point severity scale: mildly ill A ≍ 32, moderately ill ≍ 44, markedly ill ≍ 55, and severely ill ≍ 70 when correlated to the CGI (Clinical Global Impressions Scale; see Table e81-1)	The anchored BPRS provides descriptions of each severity rating to increase the interrater reliability. The BPRS has four clusters of symptoms: thinking disturbance, anxious depression, withdrawal-retardation, and hostility-suspiciousness.
Positive and Negative Syndrome Scale (PANSS)	Clinician rated	30-item, 7-point severity scale: mildly ill ≍ 57, moderately ill ≍ 75, markedly ill ≍ 95, and severely ill 116 when correlated to the CGI	Based on the 18-item BPRS for assessing the presence or absence of positive and negative symptoms, and psychopathology of schizophrenia.
Scale for the Assessment of Positive Symptoms (SAPS)	Clinician rated	34-item, 6 point severity scale. Items rated 0-5 (0 = none, 5 = severe). 30% improvement commonly used as a benchmark for response.	Commonly used in clinical trials or clinically along with the SANS. Assesses bizarre behavior, delusions, hallucinations, and thought disorder.
Scale for the Assessment of Negative Symptoms (SANS)	Clinician rated	25-item, 6 point severity scale. Items rated 0-5 (0 = not at all, 5 = severe)	Commonly used in clinical trials or clinically along with the SAPS. Five domains assessing different features of negative symptoms (blunted affect, alogia, avolition, anhedonia, and attention)
Calgary Depression Rating Scale (CDSS)	Clinician rated	9-item, 4 point severity scale. Items rated 0-3 (higher scores indicate greater symptom severity) to assess depressive symptoms in patients with schizophrenia.	Valid and reliable scale for assessing depression in schizophrenia. A score above 6: 82% specificity and 85% sensitivity for predicting a major depressive episode. https://cumming.ucalgary.ca/research/calgary-depression-scale-schizophrenia/home.

Data from References 30,79–84.

TABLE e81-4

Depression and Bipolar Disorder Rating Scales

Rating Scale	Type	Scoring	Comments
Hamilton Depression Rating Scale (HAM-D or HDRS)	Clinician rated	17-item, 0-7 no depression; 8–16 = mild depression; 17-23 = moderate depression; >23 = severe depression	Used to screen patients for clinical studies and to determine severity of symptoms and treatment outcome. HDRS is the standard to compare other depression rating scales against.
Montgomery–Asberg Depression Rating Scale (MADRS)	Clinician rated	10-item, 7-point scale. For each item: 0 = no symptoms; 6 = severe symptoms	Differentiates among all the intermediate grades of depression. Decreases bias in patients with other medical illnesses and increased somatization (varied unexplained physical symptoms).
Beck Depression Inventory (BDI)	Patient rated	21-item, 0-9 = normal; 10-15 = mild depression; 16-19 = mild-moderate; 20-29 = moderate-severe; 30-63 = severe depression	The standard for depression self-rating scales and an objective measure of change in symptoms as a result of treatment.
Zung Self-Rating Depression Scale (ZSDS)	Patient rated	20-item, 4-point severity scale: <50 = normal; 50-59 = minimal-mild; 60-69 = moderate-marked; ≥70 severe depression	Severity rated by frequency of occurrence of symptoms. May not be as sensitive in measuring changes in severity of symptoms.
Patient Health Questionnaire (PHQ-9)	Patient rated	9-item, 4-point scale. For each *DSM-IV* depression criteria item: 0 = not at all; 3 = nearly every day. Score <10 = minimal depression symptoms	Commonly used in primary care to establish a diagnosis of depression and assess severity of depressive symptoms.
Quick Inventory of Depressive Symptomatology (QIDS-C [Clinician] and QIDS-SR [Patient])	Clinician and patient rated	16-item, scores range 0-27; 0-5 = none; 6-10 = mild; 11-15 = moderate; 16-20 = severe; 21-27 = very severe	Used to assess symptom severity and symptomatic change. QIDS-SR found to be as sensitive to symptom change as the HDRS. Has usefulness in both clinical and research settings.
Young Mania Rating Scale (YMRS)	Clinician rated	11-item, 5-point severity scale: 13 = minimal; 20 = mild; 26 = moderate; 38 = severe	Used to screen patients for clinical studies and to determine severity of symptoms and treatment outcome. YMRS is the standard to compare other mania rating scales against.
Mood Disorder Questionnaire (MDQ)	Patient rated	15-item, score of ≥7 suggestive of bipolar spectrum disorder	Screens for a lifetime history of mania or hypomania. Does not assess severity of illness.

Data from References 30,85-88.

TABLE e81-5

Anxiety, Obsessive Compulsive Disorder, and Trauma and Stress- Related Disorder Rating Scales

Rating Scale	Type	Scoring	Comments
Generalized Anxiety Disorder			
Generalized Anxiety Disorder Assessment – 7 (GAD-7)	Patient rated	7-item, 3-point scale. Score of > 10 should receive further evaluation	Screens for GAD and assesses severity of illness
Hamilton Anxiety Scale (HAM-A or HAM-AS or HAMRS)	Clinician rated	14-item, 5-point scale. scores of ≥ 18-20 for moderate anxiety	Consists of subscales to measure somatic and psychic anxiety
Zung Self-Rating Anxiety Scale (Zung SAS)	Patient rated	20-item, 4-point intensity scale	Correlates to the clinician-rated Anxiety Status Inventory (ASI); however, there is little information on the validity of either test
Obsessive Compulsive Disorder			
Yale–Brown Obsessive-Compulsive Scale (YBOCS)	Clinician rated	Semistructured interview	Consists of several clusters of obsessions and compulsions; used to assess baseline severity and change in treatment studies
Panic Disorder			
Sheehan Panic and Anticipatory Anxiety Scale (SPAAS)	Patient and clinician rated	Three-part scale	Measures panic attacks, anticipatory anxiety, and limited symptom attacks
Social Anxiety Disorder			
Liebowitz Social Anxiety Scale	Clinician-rated	24-item; each item rated for fear and avoidance, both 3-point scale	Used as a diagnostic tool and assesses treatment response; will provide an overall severity assessment and an assessment of the following: performance fear, social fear, performance avoidance, and social avoidance
Trauma and Stress-Related Disorder			
Clinician Administered PTSD Scale (CAPS)	Clinician rated	30-item—structure interview; 4-point scale	Used as a diagnostic tool for current or lifetime diagnosis, severity of illness and assessment of symptoms over last week
PTSD Checklist	Patient rated	Number items dependent on version—civilian, military, *DSM-5* symptom specific; 5-point scale	Used as a screening, diagnostic tool, and assessment of treatment response

Data from References 14,15,30,89–97.

TABLE e81-6

Neurodevelopmental Disorders Rating Scales

Rating Scale	Type	Scoring	Comments
Connors 3rd Edition	Parent and Teacher rated	Three scoring options including: full-length form (most detailed), short form (when frequent monitoring is needed), and index form which is useful in screening and treatment monitoring of attention deficit hyperactivity disorder (ADHD).	Assesses inattention and hyperactivity as well as related problems in executive functioning, learning, aggression, and peer/family relations.
Aberrant Behavior Checklist for children under age 5	Caregiver rated	58-item scale to assess the presence and severity of various problem behaviors commonly observed in individuals diagnosed with intellectual developmental disabilities.	Each item is scored as 0 (never a problem), 1 (slight problem), 2 (moderately serious problem), or 3 (severe problem). Item subscales: Irritability, agitation, & crying (15 items); lethargy/social withdrawal (16 items); stereotypic behavior (7 items); hyperactivity/noncompliance (16 items); and inappropriate speech (4 items).
Children's Yale–Brown Obsessive-Compulsive Scale (CY-BOCS-PDD)	Clinician rated	Semistructured interview	This is a version of the Children's Yale–Brown Obsessive Compulsive Scale modified for pervasive developmental disorders

Data from References 106–109.

The American Psychiatric Association Practice Guidelines for the treatment of Patients with Schizophrenia recommends using quantitative measures, especially at the initial assessment, to determine the severity of psychotic symptoms (Table e81-3), functional impairments, and targets of treatment interventions.[7] For example, rating scales can assist clinicians with initial, ongoing monitoring, and management of muscle-related or extrapyramidal side-effects (EPS) (Table e81-7) including tremors (Parkinson-like symptoms), acute muscle contractions (dystonia), internal restlessness (akathisia), and tardive dyskinesia (TD) associated with antipsychotic therapy. Although beyond the scope of this chapter, there are a myriad of rating scales available to clinicians that take into account specific populations and/or characteristics such as age, gender, behaviors (eg, feeding/eating, sexual, sleep-wake, substance use, and so on), caregiver burden, quality of life/wellbeing etc.[6,30]

TABLE e81-7

Adverse Effects Measuring Instruments

Rating Scale	Type	Scoring	Comments
Abnormal Involuntary Movement Scale	Tardive dyskinesia (TD) assessment	12-item, 5-point severity scale. Items 1-4 orofacial movement; 5-7 extremity and truncal movement; 8-10 global severity; 11 and 12 problems with teeth or dentures (yes or no)	5-10 minutes to complete. Most commonly used. Diagnostic criteria: at least 3 months of antipsychotic treatment. Mild severity score (2) in two discrete areas or moderate severity (3) in one area (eg, orofacial) indicates TD. Tremor is not counted. http://www.cqaimh.org/pdf/tool_aims.pdf
Dyskinesia Identification System: Condensed User Scale (DISCUS)	TD assessment	15-item, 5-point severity scale. Items 1, 2 face; 3 eyes; 4, 5 oral; 6-9 lingual; 10, 11 head, neck, or trunk; 12, 13 upper limb; 14, 15 lower limb	5-10 minutes to complete. More descriptive criteria for scoring severity than the Abnormal Involuntary Movement Scale. Scoring based on three dimensions: frequency, detectability, and intensity. Tremor is not counted. http://hrstonline.com/wp-content/themes/healthrisk/article/DISCUS.pdf
Modified Simpson-Angus Scale (MSAS)	medication-induced Parkinson and dystonia assessments	10-item, 5-point anchored severity scale. Mean score is obtained by adding all scores and dividing by 10. A mean score of 0.3 is the upper limit for no EPS	5-10 minutes to complete. Item domains include gait, arm dropping, shoulder shaking, elbow rigidity, wrist rigidity, leg pendulousness, head dropping, eye blinking, tremor, and salivation. http://www.outcometracker.org/library/SAS.pdf
Barnes Akathisia Rating Scale (BARS)	medication-induced akathisia	4-item, including three 4-point anchored severity scored items and a 5-point global rating score item. Total score of 12 possible	10 minutes to complete. Items 1-3: objective observation of restlessness, subjective awareness of restlessness, and subjective distress related to restlessness. Diagnostic criteria: require both objective and subjective ratings of at least one in either two subjective items. http://outcometracker.org/library/BAS.pdf

EPS, extrapyramidal symptoms.

Data from References 30,98,99.

In summary, patient- and clinician-rated scales are widely used in psychiatric research and can be very valuable to both patients and patient care providers in the clinical setting by providing a consistent and objective framework to assess and to monitor treatment outcomes and medication effectiveness and safety for most psychiatric illnesses.[7,30,31,77–84,86–93,98–104]

Neuropsychiatric Rating Scales

Neuropsychiatric rating scales provide specific information, such as the rate of change and severity of cognitive decline or improvement. They are useful when repeated measurements of a patient's mental status are needed because they allow the clinician to determine response to an intervention (eg, medication) in a more systematic manner. In addition, some cognitive function measures are useful screens for neurocognitive disorders (eg, Alzheimer's disease). A number of cognitive rating scales are available, the most common being the MMSE.[23]

The MMSE is a structured interview that globally assesses many cognitive domains, including orientation, visuospatial organization, memory, and reasoning, to determine an overall score of cognitive function. The maximum score is 30, and a score of 23 or less is indicative of significant cognitive impairment. The MMSE takes 5 to 10 minutes to administer and is used routinely in the clinical setting.[94] Other examples of cognitive rating scales include the Blessed Information Memory Concentration test (BIMC), the Dementia Rating Scale (DRS-2), the Clock Drawing test (CDT), and Alzheimer Disease Assessment Scale (ADAS).[15,94–96,105]

Most of the rating scales involve a structured interview that requires clinician training to ensure accurate administration. Noise and distraction can affect the patient's performance ability; therefore, the interview should be conducted in a quiet area with adequate lighting. The interviewer should speak slowly and clearly to the patient when providing instructions and asking questions.

PSYCHOLOGICAL TESTING

Although most nonpsychology trained clinicians do not administer psychological testing, the results from these types of assessments can be used to evaluate the role of medication in relationship to the diagnosis. Psychological testing alone cannot establish a firm diagnosis but can be a useful diagnostic tool when coupled with clinical judgment. Types of psychological testing include personality tests (eg, Minnesota Multiphasic Personality Inventory-2), intelligence tests (eg, Wechsler Adult Intelligence Scale—Revised, Wechsler Intelligence Scale for Children—Revised), and neuropsychological tests (eg, Bender Visual Motor Gestalt Test).[21,23,24] Neuropsychological and intellectual assessments generally require special training or a patient referral to a specialist, such as a licensed psychologist or neuropsychologist, and should not be confused with psychiatric rating scales, which can be administered by most clinicians. As with physical examinations, laboratory results, and rating scale scores, psychological test results are best used as only one part of a comprehensive diagnostic plan.

CONCLUSION

Healthcare providers with psychiatric assessment skills may be more likely to identify overlapping physical and mental health problems, initiate psychotropic medication therapy, and/or refer their patients for additional psychiatric services to improve overall health outcomes and save lives. Hopefully, evidence-based practices and provider reimbursement for integrated behavioral health services will incentivize healthcare systems to consistently provide integrated and unified psychiatric and primary care services for all patients. In the meantime, clinicians are encouraged to seek advanced suicide prevention and psychiatric assessment training to reduce the rising rates of deaths by suicide and address negative health outcomes due to comorbid psychiatric conditions.

ACKNOWLEDGMENTS

The authors are grateful to Carolyn Phelps, PhD, DreamLife Psychological Services, for her assistance with reviewing the sections on mental status examination and psychological testing.

SELF-ASSESSMENT QUESTIONS

1. Which resource is helpful in identifying the diagnostic criteria for schizophrenia?

A. *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*)

B. American Psychiatric Association Practice Guidelines for Psychiatric Evaluation

C. Mini-Mental State Examination (MMSE)

D. Brief Psychiatric Rating Scale (BPRS)

2. Which term *best* describes the ability of a psychiatric rating scale to determine if a symptom or disorder is absent when the patient does not have the related condition?

A. Reliability

B. Validity

C. Sensitivity

D. Specificity

3. The primary care clinic providers would like to implement a depression screening tool. The scale needs to be completed by the patient in a short amount of time while waiting to see the clinician. Results would then be assessed by the clinician to determine risk of depression. Select the *most* appropriate rating scale for depression based on this practice setting.

A. Hamilton Depression Rating Scale (HDRS)

B. Montgomery–Asberg Depression Rating Scale (MADRS)

C. Clinical Global Impressions Scale (CGI)

D. Patient Health Questionnaire (PHQ-9)

4. A patient is experiencing the following symptoms: inability to sit still, pacing, feelings of inner restlessness. No other unusual muscle movements are observed such as tremors, twitching, or rigidity. Patient does not complain of any anxiety or being worried about anything in particular. The patient was started on an antipsychotic 2 weeks ago. Which rating scale would be the *most* appropriate to assess these symptoms?

A. Abnormal Involuntary Movement Scale (AIMS)

B. Barnes Akathisia Scale (BAS)

C. Dyskinesia Identification System: Condensed User Scale (DISCUS)

D. Modified Simpson-Angus Scale (MSAS)

5. The clinician asks a patient with a history of schizophrenia the following question during the clinical interview: “Do you feel that people plot against you?” Which target symptoms of schizophrenia is this question addressing?

A. Auditory hallucinations

B. Thought broadcasting

C. Paranoid delusions

D. Grandiose delusions

6. Which statement is *true* regarding a psychiatric history obtained during the clinical interview?

A. History of the patient's highest level of functioning or "baseline" does not influence treatment goals.

B. Psychiatric history should include both the patient's and patient's family history.

C. Family history of medication response does not influence medication selection.

D. Only the description of the current psychiatric episode influences the diagnosis.

7. Which statement is *true* regarding medical comorbidities in a patient with severe persistent mental illness (SPMI) compared to the general population?

A. Patients with SPMI receive the same level of medical care as the general population.

B. Patients with SPMI have an overall lower prevalence of modifiable risk factors.

C. Patients with SPMI have a shortened life span compared to the general population.

D. Diabetes risk is higher in the general population compared to patients with SPMI.

8. Which statement correctly describes a limitation associated with the use of psychiatric rating scales in the clinical setting?

A. Some clinician-rated scales require a substantial time commitment to administer.

B. Psychiatric rating scales are less useful in the clinical setting than the research setting.

C. Rating scales do not provide evidence of longitudinal changes in severity of illness.

D. Rating scales are only helpful when used initially to diagnose a mental illness.

9. A 21-year-old patient with no previous history of mental illness is admitted to the inpatient psychiatry unit with a recent acute change in mental status. Upon examination it is noted that the patient is paranoid, irritable, confused, and complains of hearing threatening voices. Which question below may best alerts the clinician to further assess an acute safety concern?

A. How often do you cry without any reason?

B. What do the voices tell you to do?

C. Describe your sleep at night?

D. Do you feel that people plot against you?

10. A patient with moderate major depressive disorder with recurrent episodes (F33.1) presents with the chief complaint that "My Prozac stopped working." Past medication history reveals multiple trials with antidepressants with temporary benefit and/or intolerable adverse effects resulting in interrupted drug therapy. The patient asks the provider about getting genetic testing to find "a medication that works." Complete the statement that *correctly* describes what the patient should expect from pharmacogenetic testing and subsequent results? Pharmacogenetic testing ______________________________.

A. Is now affordable to all patients and reimbursed by most medical insurance carriers.

B. Can explain how a person's genes may either increase or decrease the liver's ability to metabolize certain medications and help explain lack of therapeutic benefit (eg, rapid and ultra-rapid metabolizers) or side-effects (eg, reduced and poor metabolizers).

C. Identifies medications that are contraindicated due to side-effects and are most likely to be effective for the patient.

D. Can explain how a person's genes affect antidepressant medication activity (ie, mechanism of action) at the target receptor level to explain lack of therapeutic benefit or adverse effects (eg, increasing or decreasing serotonin activity in the brain).

11. The following finding is identified during a mental status examination: The patient described feeling sad and hopeless; but smiled inappropriately throughout the interview. Which section of the mental status examination should this observation be documented?

A. Mood and affect

B. Evaluation of cognition

C. Insight and judgment

D. Thought and perceptual disturbances

12. Which statement is *true* regarding the mental status examination (MSE)?

A. It is based only on observation of the patient.

B. It is a shorted version of the mini-mental status examination (MMSE).

C. It provides a systematic method of organizing and reporting current behaviors, thoughts, perceptions and functioning.

D. It should be used independently of other assessments to identify the presenting illness and contributing factors.

13. Which communication technique has been found useful in working with a patient who becomes angry and defensive after your inquiry about suspected alcohol or substance use?

A. Requesting for a release of information to contact a significant other

B. Closed-ended questioning followed by open-ended questioning

C. A motivational interview technique called "roll with resistance"

D. An interview technique that only utilizes passive listening and reflection

14. A 91-year-old nursing home patient presents to the emergency department with recent mental status changes including dizziness, confusion, and aggression over the past two days. The patient scored an 18 (moderate cognitive impairment) on the mini-mental status examination (MMSE). In addition to the mental status examination (MSE), what additional information is needed to complete a thorough evaluation?

A. Blood chemistry, complete blood count, and urinalysis

B. Hamilton Depression Rating Scale (HDRS) score

C. Electrocardiogram and pharmacogenetic testing

D. Patient Health Questionnaire (PHQ-9) score

15. A 6-year-old student has been having behavioral problems in the classroom that are very disruptive to the other students and affecting his scholastic performance. The parents have noticed some of these behaviors at home; but, were hoping they would go away. His behavior consists of leaving his seat without permission, climbing on the classroom desks and windows, unable to finish homework, forgetful, and loses assignments on multiple occasions. The family practice provider is considering the diagnosis of attention deficit hyperactivity disorder. Which test or assessment to help clarify this patient's diagnosis requires special training or patient referral to a specialist, such as a licensed psychologist or neuropsychologist?

A. Children's Yale–Brown Obsessive Compulsive Scale modified for pervasive developmental disorders

B. Mini-Mental State Examination

C. Wechsler Intelligence Scale for Children—Revised

D. Connors 3rd Edition

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) provides a common language for practitioners to describe and diagnose psychiatric disorders (see section: Overview of Diagnostic Classification Systems Used in Psychiatry).

2. **D.** Specificity is the correct answer and refers to a test's ability to correctly determine that a symptom or illness is absent when the person does not have the illness. For example, a test with 90% specificity correctly reports 90% of patients without the illness, but 10% patients without the illness are incorrectly identified as false positives (see section: Measurements of Psychiatric Symptoms and Cognitive Function).

3. **D.** Patient Health Questionnaire (PHQ-9) is a patient-rated scale that can be completed by the patient in the waiting area. The other scales are clinician-rated scales that are typically completed during or shortly after the patient encounter (see Table e81-4).

4. **B.** Barnes Akathisia Scale (BAS) allows the clinician to determine the severity of a patient's inability to sit, pacing, and internal restlessness which is a side-effect of antipsychotic agents known as akathisia. The Modified Simpson-Angus Scale is used to assess parkinsonian-like side-effects (eg, tremor, slowed gait) and both Abnormal Involuntary Movement Scale and Dyskinesia Identification System: Condensed User Scale monitor for movements suggesting tardive dyskinesia (see Table e81-7).

5. **C.** Paranoid delusions are fixed or unshakable false belief, fear, or feeling that there is a plot or scheme aimed at the person to cause physical and/or psychological harm. Although auditory hallucinations sometimes may be described as frightening or threatening voices, this would not be referred to as a delusion. Hallucination are symptoms that are associated with one or any of the five senses (hearing, sight, taste, touch, and smell). Thought broadcasting is when a person believes that others around them can actually hear the person's thoughts or able to "read" their mind (see sections: Mental Status Examination [Thought and Perceptual Disturbances]).

6. **B.** Psychiatric history needs to include both the patient's and patient's family history. This information can be used to establish a baseline or the highest level of function that does influence the treatment goals. Family history of medication response can affect medication selection. The clinician needs both current and past psychiatric episodes including hospitalizations and other events related to acute psychiatric symptoms (eg, suicidality, substance intoxication, and so on) (see sections: Psychiatric History and Medication History).

7. **C.** Patients with SPMI have shortened life span compared to the general population due to lack of medical care, behavioral risk factors (eg, suicide, tobacco/substance use), and chronic diseases such as diabetes (see section: Physical Assessment).

8. **A.** Clinician-rated scales can take substantial time to administer and complete. However, psychiatric rating scales can help estimate presence and severity of symptoms during initial diagnosis and also provide a consistent approach to monitoring symptoms over time (longitudinal changes) (see section: Measurements of Psychiatric Symptoms and Cognitive Function).

9. **B.** What do the voices tell you to do? The clinician must determine the content of the auditory hallucinations if possible. For example, there is an increased risk of suicide/homicide if auditory hallucinations are commanding the patient to harm themselves or other. Command hallucinations can necessitate the need to escort the patient to the emergency department to assess safety and possible hospitalization (see Table e81-2).

10. **B.** Although pharmacogenetic testing can identify potential genes that may affect a medication's mechanism of action, most of the pharmacogenetics research evidence focuses on how genes affect liver enzymes (ie, cytochrome P450 enzymes) and drug metabolism. Pharmacogenetic testing can determine if the person's P450 liver enzyme activity is normal, rapid, reduced, or lacking activity (eg, poor metabolizer). Pharmacogenetic testing can provide guidance to the clinician and patient around medication selection; but pharmacogenetic test results do not provide a definitive list of all medications that are contraindicated or guaranteed to be effective. Pharmacogenetics testing is expensive and not covered by all medical insurance companies (see section: Laboratory Assessment).

11. **A.** The clinician would document in the mental status examination's section that the patient's mood and affect is depressed with incongruent

smiling. This information can help clarify a diagnosis, since one would expect that a person with depression would appear sad or have a sad affect. In this case, the clinician is likely to explore other underlying symptoms such as anxiety, delusions, and other cognitive distortions (eg, auditory hallucinations) to explain the inappropriate smiling. (see sections: Mental Status Examination [Affect and Mood]).

12. **C.** The mental status examination provides a systematic method of organizing and reporting current behaviors, thoughts, perceptions, and functioning. The mental status examination pulls together all of the information gathered during the patient encounter including recent history, contributing factors, direct observation of the patient, and other findings (eg, laboratory findings, behavioral rating scale results, and so on) (see sections: Mental Status Examination).

13. **C.** The motivational interview technique called "roll with resistance" can de-escalate a person who is angry and defensive when the interviewer does not react negatively to a patient's anger. Although listening and reflection can be effective, it should not be the only technique utilized (see section: Laboratory Assessment).

14. **A.** Based on the recent mental status changes, observations of the patient, and MMSE finding, a thorough medical assessment including laboratory tests (eg, blood chemistry, complete blood count, and urinalysis) is needed to rule out possible delirium due to possible infection or other medical conditions to explain the acute decrease in cognitive function (see section: Laboratory Assessment).

15. **D.** Psychological testing utilizing the Wechsler Intelligence Scale for Children—Revised can help clarify this patient's diagnosis and needs to be administered by a trained provider such as a psychologist. The obsessive compulsive disorder assessment might be helpful if the family provider was considering obsessive compulsive disorder (OCD) instead of the diagnosis of attention deficit hyperactivity disorder (ADHD). The mini-mental state examination (MMSE) is reserved for adult patients to assess alertness, speech, cognition, and memory. The Connor's 3rd edition is a parent–teacher-rating scale that can be used in the home or school setting to assess observed symptoms of ADHD (see Table e81-6).

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter e83: Eating Disorders

Steven C. Stoner; Valerie L. Ruehter; Melissa C. Palmer

KEY CONCEPTS

KEY CONCEPTS

① Eating disorders are more commonly recognized than years past although patients are likely to not seek help and medication treatment options are limited.

② Symptoms common to eating disorders include excessive intake of calorie-laden food over a short period of time (eg, binge eating or bingeing), and inappropriate compensatory behaviors to expend calories such as self-induced vomiting, the overuse of laxatives, diuretics, enemas, fasting, or excessive exercise (eg, purging behaviors).

③ Shifting between different eating disorder diagnostic categories is possible, especially if treatment does not result in symptom remission.

④ Psychiatric comorbidities are common with all forms of eating disorders. The differential diagnosis should generally include evaluation for depression, schizophrenia, generalized anxiety, obsessive-compulsive disorder (OCD), and personality disorders.

⑤ Calories must be gradually introduced during caloric restoration to prevent the potentially fatal complication known as refeeding syndrome. Failure to restore calories quickly enough may result in an unfeeding syndrome.

⑥ Clinicians must monitor closely for suicidality and educate individuals appropriately, similar to patients with major depressive disorder taking antidepressants, as mortality from suicide is not uncommon.

⑦ The treatment approach for anorexia nervosa (AN) includes a minimum of 6 months of psychotherapy, preferably cognitive behavioral therapy (CBT), in adults and family-based therapy in children. There are no FDA-approved agents for the treatment of AN.

⑧ Despite limited data, antidepressants in combination with nonpharmacologic treatment are the preferred pharmacotherapy for the acute and maintenance phases of bulimia nervosa (BN). Fluoxetine is the only FDA-approved medication to treat adult BN.

⑨ Use of selective serotonin reuptake inhibitors (SSRIs) and topiramate for the treatment of binge-eating disorder (BED) along with CBT and interpersonal psychotherapy (IPT) is supported by the literature. Lisdexamfetamine is the sole FDA-approved agent for BED.

⑩ It is important to transition patients being treated for AN gradually to outpatient care as there is a high risk of relapse within the first 60 days of inpatient refeeding.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “After Anorexia: Life’s too short to weigh your cornflakes” (*https://www.youtube.com/watch?v=gZpcTVqpaPw*) a TEDx Talk from Catherine Pawley, a patient recovering from anorexia. In this 8-minute video you will hear a brief overview of one person’s experience with anorexia nervosa and will enhance understanding of the symptoms and emotional challenges associated with eating disorders. This video will also enhance understanding regarding the COLLECT and ASSESS part of the Patient Care Process.

INTRODUCTION

Eating disorders are widely accepted as serious mental illnesses. The spectrum of eating disorders encompasses several complex diseases, with most sharing the pathologic feature of overvaluation of body shape and weight. Eating disorders arise from the complex interaction between environmental, societal, developmental, psychosocial, genetic, and biologic factors. About 5 to 10 million females and 1 million males in the United States alone have an eating disorder. The urbanization of society, social pressure, and obsession with perfection and being thin have led to an increasing prevalence of eating disorders, with a median age of onset between 18 and 21 years, though estimates in adolescent studies suggest median ages of onset between 12 and 13 years.[1,2] Anorexia nervosa (AN), bulimia nervosa (BN), and binge-eating disorder (BED) are the most prevalent forms of eating disorders.[3]

① Despite an improved understanding of these cognitively and emotionally disabling, and potentially fatal disorders, treatment remains difficult. Patients with eating disorders often demonstrate social difficulties prior to the onset of illness.[4] Pharmacologic intervention is a small part of a comprehensive treatment plan that emphasizes psychotherapy to address some of the social challenges, notably cognitive behavioral therapy (CBT) in adults and family therapy in younger patients.

EPIDEMIOLOGY

Anorexia Nervosa

Anorexia Nervosa (AN) impacts an estimated 0.9% to 2% of females in the United States. It usually presents during adolescent years (median onset 12.3 years of age) and 90% of the cases involve adolescents and young adults.[1,2] The estimated 12-month prevalence of the disorder in the general population is 0.4% of females with a smaller percentage in males.[2,3] Longitudinal management of AN is difficult, as patients are often resistant to weight restoration plans, and psychiatric comorbidities exist in over 50% of those with AN.[2] Rates of relapse requiring hospitalization within 1 year exceed 30%, and crude mortality rates are estimated at 15% for males and 5% for females.[5-7]

The promotion of the virtues of being thin is also a potentially negative environmental factor. Many “pro-anorexia” social media outlets inappropriately promote healthy lifestyle aspects of anorexia and being thin as a means of being in control and successful, while also serving as a means of support.[8]

Bulimia Nervosa

Bulimia nervosa (BN) usually presents in later adolescence or early adult life and similar to AN, 90% of cases are in adolescents a young adults.[2] Between 1% and 4.6% of adolescent and young adult females meet the diagnostic criteria for BN, with lifetime prevalence estimates of 1.5% in females and 0.5% in males.[1-3,9]

Binge-Eating Disorder

BED often presents in adolescence but can also emerge later in life.[3] Overall, BED is more common in females with a lifetime prevalence of 2% to 3.5% in adults and an approximate prevalence of 1% to 5% in adolescent-based studies utilizing the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*, see Chapter e81, “Evaluation of Psychiatric Illness”) criteria.[10,11] The 12-month prevalence rate is an estimated 0.44%-1.6%.[12,13]

Other Specified and Unspecified Feeding and Eating Disorders

According to the *DSM-5*, additional diagnostic categories of specified and unspecified feeding and eating disorders exist where symptoms result in distress, but do not meet the full diagnostic criteria of specific feeding or eating disorders.[3] Examples listed within these categories include atypical AN, BN (lower frequency), BED (lower frequency), purging disorder, and night-eating syndrome (NES).[3]

NES is common in obesity clinic populations and is often accompanied by depressive symptoms. The syndrome is defined by repetitive night eating that includes eating after having been asleep or excessive food consumption following evening meals.[3,14] Night eating affects an estimated 1.5% of the general population with a high prevalence of obesity and psychiatric comorbidities.[15] Patients with NES are reported to benefit from antidepressant therapy, most notably sertraline 50 to 200 mg daily or escitalopram 5 to 20 mg daily.[14,15] Cognitive behavioral therapy may also be of benefit in NES, particularly in promoting weight loss.

Additionally, the *DSM-5* includes Pica, Avoidant/Restrictive Food Intake Disorder, and Rumination Disorder as stand-alone diagnoses within Feeding and Eating Disorders.[3]

ETIOLOGY

The exact etiology of eating disorders remains unknown and is likely multifactorial including genetic, biologic, developmental, and environmental mechanisms. While it is clear that brain reward mechanisms are altered, the exact biologic basis for eating disorders is difficult to delineate.

PATHOPHYSIOLOGY

Structural and functional brain imaging studies utilizing computed tomography (CT) and magnetic resonance imaging (MRI) have yielded a number of inconclusive findings. Anorexia nervosa has been linked with the development of enlarged cortical sulci, ventricles, interhemispheric fissure, and reductions in gray matter (amygdala, hippocampus, cingulate cortex, and putamen). Dystrophic abnormalities in the cerebrum have also been noted with weight loss, though normalization occurs with weight gain.[16] Abnormalities of the hypothalamic–pituitary–gonadal, hypothalamic–pituitary–adrenal, and hypothalamic–pituitary–thyroid axes are described as potential causes of AN. Amenorrhea is found in the majority of females with anorexia, providing support for the association with gonadotropin.[3,9]

Serotonin, norepinephrine, opioid, and dopamine neurotransmission and receptors have been studied extensively with varying roles in controlling eating behaviors. Special emphasis has been placed on the role of serotonin (5-HT), specifically noting reduced cerebrospinal fluid (CSF) basal concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of 5-HT, as well as increased binding of 5-HT1A receptors and reduced binding of 5-HT2A receptors in different regions within the central nervous system (CNS). Reduced dietary intake of tryptophan-containing foods leads to reduced levels of tryptophan, a requirement for 5-HT development.[17-19] 5-HT and dopamine function remain abnormal after weight restoration, with 5-HT activity being abnormally high in patients recovered from AN, while 5-HT2A receptors are reduced and dopamine receptors are increased following recovery.[18-20]

During acute phases of illness, BN and BED have been linked to hypoactivity of the frontostriatal circuits, abnormal amygdala response, diminished attentional capacity, and increased regional cerebral blood flow secondary to eating disorder-relevant stimuli.[21]

Complicating the study of these abnormalities is that their dysfunction is thought to be secondary to weight loss. Ghrelin, an amino-acid peptide produced by the stomach but centrally acting to promote food intake, is a current area of research focus.[22] Brain-derived neurotrophic factor (BDNF) is another protein of interest both eating and mood disorders.[20]

There are strong genetic influences in AN, and likely associations in both BN and BED as well. In addition, there is a high degree of premorbid anxiety and obsessive tendencies, which are also symptoms of disorders with suspected genetic associations. There is concordance of approximately 55% and 35% in monozygotic twins and 5% and 30% in dizygotic twins for AN and BN, respectively.

Genetic-based linkage studies offer hope for a future role of personalized medicine in eating disorder treatments, as numerous investigations have examined predictors for developing AN. Studies to date have identified possible associations with chromosomes 1, 2, 3, 4, and 13; however, studies are limited by low sample size and results have not been consistent.[18,23,24] Some investigations have focused on polymorphisms of the 5-HT2A receptor and presence of low-function alleles associated with the 5-HT transporter (*5-HTTLPR, SLC6A4*) in combination of the 5-HT2A receptor gene (–*1438G/A*) suggest an association with poor treatment response.[25,26] Additional study has focused on the estrogen receptor I gene (ESRI) with the restrictive form of AN.[27] The polymorphism with the most significant association with BED to date is Taq1A.[28]

Emphasis is also placed on environmental factors such as social stress and psychological and developmental issues related to dysfunctional family relationships that may trigger abnormal eating behaviors. Athletes are at risk for eating disorders, include gymnasts, ballet dancers, figure skaters, distance runners, swimmers, wrestlers, and body builders.[29]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Anorexia Nervosa

General

- Restriction of energy intake that leads to low body weight and self-evaluation that is influenced by perceptions of weight and body shape

Symptoms

- Obsessions and fears about eating and gaining weight
- Complain about feeling full even when they have eaten very little food
- Denial of symptoms, failure to recognize low body weight, and low self-esteem
- Feelings of ineffectiveness and lack of self-control

Signs

- Weakness, lethargy, cachexia, amenorrhea, vomiting, restricted food intake, inappropriate exercise, delayed sexual development, edema, delayed gastric emptying, constipation, abdominal pain, bradycardia, hypotension, osteoporosis, dry cracking skin, lanugo, callus on dorsum of hand, cold intolerance, perioral dermatitis, and erosion of dental enamel

Laboratory Abnormalities

- Hypokalemia, hypochloremia, hypothyroidism, hypophosphatemia, hypokalemic alkalosis, hypomagnesemia, metabolic acidosis, blood urea nitrogen, hepatic enzymes, leukopenia, thrombocytopenia, anemia, QT interval prolongation, bradycardia, hypercholesterolemia, and bone mineral density

Other Diagnostic Tests

- Nonspecific electroencephalogram (EEG) changes

CLINICAL PRESENTATION: Bulimia Nervosa

General

- Binge-eat which stops with abdominal pain or self-induced vomiting or interruption by another person
- Pattern of severe dieting followed by binge-eating episodes
- Concerned about body image but do not have the drive to thinness, which is a characteristic of AN

Symptoms

- Do not eat regular meals and do not feel satiety at the end of a meal
- May use purging methods such as laxatives for weight control
- Feelings of guilt, depression, and self-disparagement after binges
- Social isolation can result from frequent bingeing
- Chaotic and troubled personal relationships and substance use are common

Signs

- Bingeing, vomiting, salivary gland inflammation, erosion of dental enamel, callus on dorsum of hand, perioral dermatitis, dental caries, parotid gland enlargement, abdominal pain, upper end of normal body weight or slightly overweight, frequent weight fluctuations, and diminished masticatory ability

Laboratory Abnormalities

- Hypokalemia, hypochloremic metabolic acidosis, and elevated serum amylase

Other Diagnostic Tests

- None

CLINICAL PRESENTATION: Binge-Eating Disorder

General

- Repeated episodes of binge-eating that includes a lack of self-control and eating an amount of food that is beyond what most people would eat
- Episodes of binge-eating may include rapid eating, a sense of fullness to the point of being uncomfortable, eating when not hungry, eating alone secondary to feeling embarrassed, and a sense of self-disgust, depression, or guilt

Symptoms

- Episodes of binge-eating
- Lack of self-control
- Rapid consumption of food
- Feeling full and eating when not hungry
- Isolation and guilt/depression

Signs

- Obesity
- History of weight loss followed by weight gain
- Binge-eating without compensatory purging
- Comorbid psychiatric (eg, depression, anxiety, ADHD, insomnia) and medical complications (eg, GERD, hypertension, pain disorders, dyslipidemia, and asthma)

Laboratory Abnormalities

- Elevated lipids, glucose, and hemoglobin A1C, abnormal electrolytes, and increased weight

Other Diagnostic Tests

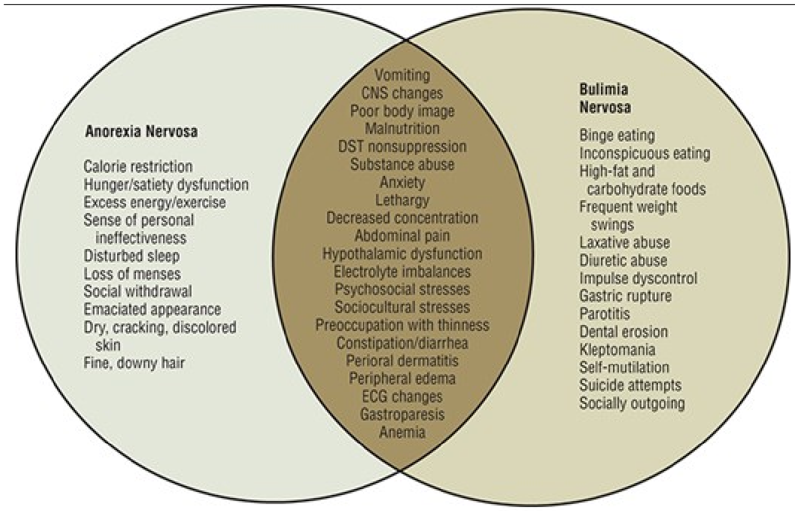
- None

②Symptoms common to all eating disorders include excessive intake of calorie-laden food over a short period of time (eg, binge eating or bingeing), and inappropriate compensatory behaviors to expend calories such as self-induced vomiting, the overuse of laxatives, diuretics, enemas, fasting, or excessive exercise (eg, purging behaviors).

③ Anorexia nervosa and BN occur together in ~30% to 64% of patients with eating disorders, thus appearing as a continuum of symptoms making careful medical and psychiatric assessment at baseline essential.[30] Patients who initially present with either AN or BN may alternate from one disorder to the other, especially in cases where remission is not achieved. Figure e83-1 demonstrates similar and unique features of both disorders. Adolescent and adult males may present with body image concerns skewed toward masculinity.[31]

FIGURE e83-1

Signs and symptoms of anorexia nervosa and bulimia nervosa. (DST, dexamethasone suppression test; ECG, electrocardiogram)



Anorexia Nervosa
Calorie restriction
Hunger/satiety dysfunction
Excess energy/exercise
Sense of personal ineffectiveness
Disturbed sleep
Loss of menses
Social withdrawal
Emaciated appearance
Dry, cracking, discolored skin
Fine, downy hair
Vomiting
CNS changes
Poor body image
Malnutrition
DST nonsuppression
Substance abuse
Anxiety
Lethargy
Decreased concentration
Abdominal pain
Hypothalamic dysfunction
Electrolyte imbalances
Psychosocial stresses
Sociocultural stresses
Preoccupation with thinness
Constipation/diarrhea
Perioral dermatitis
Peripheral edema
ECG changes
Gastroparesis
Anemia
Bulimia Nervosa
Binge eating
Inconspicuous eating
High-fat and carbohydrate foods
Frequent weight swings
Laxative abuse
Diuretic abuse
Impulse dyscontrol
Gastric rupture
Parotitis
Dental erosion
Kleptomania
Self-mutilation
Suicide attempts
Socially outgoing

The use of purging methods is not limited to BN and self-induced vomiting is the most common form of purging behavior.[32] Laxative overuse is another form of purging common in both AN and BN, used by an estimated 3% to 70% of patients.[32-34] Although ineffective as a weight-loss strategy, laxative overuse is often done in combination with other behaviors, including exercise, diuretics, enemas, and saunas. Within the diagnostic framework of AN, laxative overuse is most common in those identified with the purging subtype.[32] Psychiatric symptoms of depression, anxiety, and borderline personality disorder are also reported in those who overuse laxatives.[32-34]

Depression, schizophrenia, obsessive-compulsive disorder (OCD), and conversion disorders should be included in the differential diagnosis of AN, BN, and BED as eating abnormalities can be a component or share similar symptoms of these illnesses. The salient differences are the overriding drive for thinness, disturbed body image, increased energy directed at losing weight, and binge-eating episodes that are relatively specific for eating disorders. Most patients with eating disorders experience relief of psychiatric symptoms on refeeding.[35]

Anorexia Nervosa

The presentation of AN includes a recent period of weight loss and associated behaviors to promote this weight loss, such as vomiting, limiting food intake, and excessive exercise. Current diagnostic criteria for AN include the restriction of energy intake relative to requirements, which leads to low body weight contextually as it relates to age, sex, developmental trajectory, and physical health.[3] The *DSM-5* further classifies AN as restricting type in which patients restrict food intake with no binge-eating or purging behavior over the past 3 months, or binge-eating/purging type, in which patients regularly participate in bingeing or purging over the prior 3 months.[3] The severity of AN is based upon body mass index (BMI) in adults and BMI percentiles in children and adolescents. Comorbid psychiatric conditions, such as major depression, are frequent but should initially be considered secondary to starvation and not a true mood disorder. Specific risk factors for AN include female sex, having a sibling with AN, the presence of mood disorders in family members, and comorbid anxiety, personality, or substance use disorders.[36]

④ Psychiatric comorbidity is common, as up to 75% of patients have a primary mood disorder, and there is also an association with personality disorders and anxiety disorders, such as social phobia and OCD.[2,37] The lifetime prevalence of OCD in patients with AN is reported to be as high as 40% compared to 2.5% in the general population.[37-39] The impact that psychiatric comorbidity has on treatment outcomes of AN is unknown, but it is important to understand that deprivation of food may contribute to both mood and cognitive fluctuations.

Bulimia Nervosa

The core feature of BN is recurrent episodes of binge-eating. Most patients with BN have normal weight, although they might fluctuate between being underweight and overweight. Patients lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. These behaviors may include self-induced vomiting; overuse of laxatives, diuretics, enemas, or other medications; strict dieting or fasting; or excessive exercise. To meet *DSM-5* criteria, the binges and compensatory behaviors must occur on average at least once weekly for 3 months.[3] Bulimia nervosa can further be differentiated by purging type (regularly engages in self-induced vomiting or the overuse of laxatives, diuretics, or enemas) or non-purging type (uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not engage in purging activities).[3]

Patients with BN typically binge and vomit at least once daily. Caloric intake varies, but patients can consume between 5,000 and 20,000 cal (20,900 and 83,700 J) during a single binge and they tend to consume foods that are easy to ingest, do not require much chewing or preparation, and are high in carbohydrates or fat. Binge-eating is typically secretive and precipitated by a stressful event, followed by post-binge remorse. In general, binges often last less than 2 hours but can extend to more than 8 hours. To compensate for the excessive caloric intake, many patients fast for prolonged periods, exercise compulsively, purge, or overuse laxatives.

Psychiatric comorbidity for BN includes depression (up to 80%), poor impulse control, and substance use. Approximately 30% to 37% of patients diagnosed with BN have a personal history of substance use.[40] Kleptomania and borderline and avoidant personality disorders are also frequently observed, as patients also commonly steal laxatives and comfort items, such as candies and clothes.[9,37,41]

Binge-Eating Disorder

Patients with BED present with recurrent episodes of bingeing without the maladaptive compensatory behaviors with approximately half of patients seeking treatment.About 5% to 10% of patients seeking treatment for obesity have BED.[42] Comorbid psychiatric disorders are reported in greater than 70% of BED patients with depression and low self-esteem seen most commonly. The self-deprecating focus on body image possible with BED is less severe than in AN or BN.[39,43] Diagnostic criteria for BED requires recurrent episodes of binge-eating (eating an amount of food in a 2 hour time frame that is larger than what most people would eat in a similar situation and a sense of lack of control over eating during the episode).[3] The binge-eating episodes are associated with at least three of the following: eating more rapidly than normal; eating until feeling uncomfortably full; eating large amounts of food when not physically hungry; eating alone because of embarrassment of how much is being eaten; and feeling disgusted with oneself, depressed, or guilty after the episode. The severity of BED is determined by the number of binge-eating episodes per week (1-3 = mild; 4-7 = moderate; 8-13 = severe; 14 or more = extreme).[3]

Medical Complications of Eating Disorders

⑤ The potential medical complications of eating disorders involve multiple organ systems. The type of medical complication encountered is dependent on the type and frequency of the eating disorder behavior. Cardiac complications may occur and can include arrhythmias such as sinus bradycardia, cardiac muscle atrophy, orthostatic hypotension, decreased cardiac output, arrhythmia, and QTc interval prolongation.[44,45] During caloric restoration, there is a potential risk for developing refeeding syndrome, which can progress to fatal cardiovascular collapse. This risk is reduced by the gradual versus rapid reintroduction of calories.

Metabolic (eg, metabolic acidosis and metabolic alkalosis) and electrolyte disturbances (eg, hypokalemia, hypomagnesemia, and hypocalcemia) and dehydration are often seen. Elevations in bicarbonate levels during periods of hypokalemia can be an indication that the patient is inducing vomiting or using dietary weight-loss medications. Non-anion-gap acidosis has also been reported with the overuse of laxative agents. Additionally, both acute and chronic renal failures have been reported.

Gastrointestinal (GI), oropharyngeal, and dental complications are frequent, as are general complaints of lethargy and fatigue. Evidence of Russell's sign may be present, which is signified by skin lesions on the fingers used to induce vomiting.

Hormonal changes related to the hypothalamic–pituitary–gonadal axis resulting from starvation are often seen. These abnormalities include effects on estradiol, the gonadotropins (eg, luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone), thyroid function, adrenal function, and growth hormone.[9,44] A syndrome has been identified in female athletes and termed the "female athlete triad," defined by the development of irregular menses, osteoporosis/low bone mineral density (BMD), and disordered eating.[44,46] An athlete may experience only one or two components of the triad, or all three.[47] Because low BMD and abnormalities in hormone levels is not gender specific, the term "relative energy deficiency in sport" has been recommended to replace the "female athlete triad" designation to represent the syndrome in both female and male athletes.[48] Osteopenia and osteoporosis are potential long-term complications of suppressed estrogen. The restoration of weight, specifically in AN, reverses the bone loss, although estrogen supplementation does not appear to be effective.[49] In all cases, the preferred method to address these issues is the normalization of nutrition. The impact on female fertility is not well studied, although the ability to carry a pregnancy to term or to give birth to a child of average birth weight appears reduced.

Chronic starvation can contribute to brain atrophy; however, decreases in white matter and CSF volumes return to normal after a healthy weight is achieved, but gray matter loss can persist.[35,50,51]

Obesity is common in patients with BED and may also be present in patients with BN, placing these patients at an increased risk of medical comorbidities including type 2 diabetes mellitus, dyslipidemia, and hypertension.[30] Assessment should include measurement of weight, height, pulse rate, blood pressure, and calculation of BMI. Random glucose and ECG should be done as medically indicated.[30]

A thorough physical and laboratory evaluation, as described in Table e83-1, is essential to determine the severity of medical complications.[3,30,35,51]

TABLE e83-1

Physical and Laboratory Assessment of Eating Disorders

Evaluation	Target Symptoms
Pulse	Bradycardia, tachycardia
Blood pressure	Hypotension, orthostasis
Height/weight	Underweight for size and age/body mass index
Respiratory rate	Rapid if heart failure occurs during refeeding
Temperature	Hypothermia, cold intolerance
Electrocardiogram	ST depression, flat T waves, U waves, increased QT interval, atrioventricular block
Gastrointestinal	Hypoactive bowel sounds, gastritis, abdominal distention
Skin	Dryness, scaling, lanugo, hair loss, calluses on fingers and hands
Menses	Amenorrhea
Complete blood count	Leukopenia, anemias, thrombocytopenia
Electrolytes	Hypokalemia, hypomagnesemia, hyponatremia, hypophosphatemia, or hyperphosphatemia
pH	Metabolic alkalosis (acidosis if laxative overuse)
Amylase	Elevated; pancreatitis rare
Liver	Hypoalbuminemia, elevated γ-glutamyl transferase if alcohol misuse, elevated AST
Thyroid	Low to low normal, but not true thyroid disease
Cortisol	Elevated with lack of suppression on dexamethasone suppression test
Bone density	Osteoporosis, osteopenia
Renal	Reduced eGFR (less than 60 mL/min/1.73 m^2)
Endocrine	Hypoglycemia

Data from References 3,9,30,46-49,52.

Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, gender identity, pregnancy status)
- Patient history (past medical, family, social—dietary habits, exercise patterns, laxative use)
- Weight history and body mass index (BMI)
- Current medications and prior eating disorder treatment(s)
- Objective data
  - Blood pressure (BP), heart rate (HR), height, weight, and BMI
  - Labs (eg, serum electrolytes, serum creatinine [Scr], estimated glomerular filtration rate [eGFR], blood urea nitrogen [BUN], metabolic panel)
  - Other diagnostic tests when indicated (eg, ECG, EEG, bone mineral density)

Assess

- Symptoms of eating disorders (eg, anorexia nervosa, bulimia nervosa, and binge-eating disorder) that may include poor body image, weight change, lethargy, binging, purging, and GI complaints (Tables e83-1 and 83-2)
- Presence of mental health conditions (eg, depression, schizophrenia, anxiety disorders)
- Presence of medical conditions (eg, malnourishment, cardiac arrhythmia, refeeding syndrome, metabolic acidosis and alkalosis, dehydration, GI complications, osteopenia, osteoporosis, dental problems) (Fig. e83-1)
- Laboratory abnormalities (eg, hypokalemia, hypothyroidism, hypomagnesemia, hypophosphatemia) (Table e83-1)
- Current medications that may exacerbate eating disorder symptoms (eg, diuretics, laxatives)
- For the type of eating disorder identified, assess the appropriateness of medication therapy (see "Treatment" section)

Plan*

- Nonpharmacologic treatments (eg, nutritional rehab, education, and counseling; cognitive behavioral therapy; interpersonal psychotherapy; dialectical behavior therapy, family, and/or group therapy) (see "Treatment" section)
- Pharmacotherapy dependent upon the eating disorder identified (eg, antidepressants, antipsychotics, antiseizure medications, lisdexamfetamine) (see Fig. e83-2)
- Monitoring parameters including efficacy (eg, BP, cardiovascular events, kidney health), safety (medication-specific adverse effects), and time frame
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, pharmacotherapy)
- Self-monitoring of weight, BMI, BP, and HR—where and how to record results
- Referrals to other providers when appropriate (eg, physician, dietitian)

Implement*

- Provide patient education regarding all elements of treatment plan (nonpharmacologic and pharmacologic)
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up assessments of treatment

Follow-Up: Monitor and Evaluate*

- Changes in eating habits and compensatory behaviors (Fig. e83-1)
- Weight, vital signs, and laboratory values (Table e83-1)
- Psychiatric (mental status examination) and physical condition stability
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcomes

The goals for patients with eating disorders are to reduce distorted body image; restore and maintain healthy body weight; establish normal eating patterns; improve psychological, psychosocial, and physical problems; resolve contributory family problems; enhance adherence; and prevent relapse.[32] Specific to BED is the additional goal of weight loss, if applicable.

Anorexia Nervosa

⑥ The long-term prognosis of patients with AN is not clear, as the majority of studies focus on acute treatment. The course of the disorder most commonly consists of a single episode with subsequent return to normal weight, although patients can still experience issues with disturbed body image, disordered eating, and other psychiatric problems after weight has normalized.[35] Some patients experience an unremitting course leading to death, whereas others suffer episodically. Remission rates improve with longer treatment times, as the lowest rates are reported in shorter-duration follow-up trials, while remission rates near 80% have been reported in longer-term follow-up studies at 8 and 16 years.[53] Up to 20% of patients remain chronically ill despite weight normalization, return of menses, and improved eating behaviors.[54] Long-term prognosis is more favorable with extended follow-up care and younger age at onset, whereas a poorer prognosis is associated with chronic illness, lower initial weight, poor family relationships, obsessive-compulsive personality symptoms, and the presence of bulimia or purging behavior.[25,54,55] Crude mortality rates appear to be lower than historically projected with the estimated mortality rate being 2.8% to 4%. When death occurs, it is most often the result of cardiac arrest or suicide.[3,53,54]

Bulimia Nervosa

The prognosis of BN appears to be more favorable than that of AN. Patients with milder presenting symptoms who are treated as outpatients tend to do better, whereas those with electrolyte imbalances, esophagitis, dental caries, and salivary gland enlargement have a more complicated course.[9] The presence of psychiatric comorbidity and greater general psychiatric symptom severity has been determined to be poor prognostic indicators. Longer rates of follow-up tend to have higher rates of remission, reaching 70% or higher with 5 to 20 years of follow-up. However, even in cases in which patients respond, they continue to exhibit symptoms that wax and wane, sometimes meeting full criteria for diagnosis of BN or subthreshold forms of BN that do not meet full criteria. Total absence of symptoms is an uncommon outcome, and residual symptoms predispose disease relapse.[53] The actual definition of recovery varies, as once-a-month binge–purge episodes are considered by some to be recovery, if their episodes were previously more frequent, whereas other clinicians consider a patient recovered only when there is complete absence of these behaviors.[56]

Binge-Eating Disorder

Studies to date suggest higher remission rates (25%-80%) in 1- and 4-year follow-up studies compared with findings in AN and BN longitudinal studies. These numbers are irrespective of selected treatment. Although sex is not a significant treatment outcome moderator, males generally have lower psychopathology and lose more weight over the course of treatment.[57] Estimated crude mortality rates range from 0% to 4.7% with a cumulative mortality rate reported at 0.5%.[53,58]

General Approach to Treatment

Treatment plans are individualized based on the severity of specific core features of the eating disorder and comorbid medical and psychiatric conditions. The absence of an adequate support system of family and friends can contribute to failed treatment. A critical first step is to determine illness severity, as that drives both the intensity and the setting for delivery of care. Hospitalization is generally reserved for the most severely ill patients. In AN, lower admission BMI and the presence of purging symptoms and austerity predict longer lengths of stay.[59] Some criteria for hospitalization are outlined in Table e83-2.[3,29,35,60] Medications are part of the comprehensive treatment strategy for eating disorders, but are rarely recommended as the sole treatment.[61-63] Comparative, double-blind, placebo-controlled trials are sparse, and most are limited by small sample sizes and high dropout rates. Additionally ambivalent patient attitudes toward treatment, and medical complications complicate interpretation of these studies.[64]

TABLE e83-2

Considerations for Hospitalization of Patients with Eating Disorders

- Rapid weight loss or Body Mass Index (BMI) less than 12
- Reduced oral intake of food (sudden and persistent)
- Medical complications (eg, edema) and metabolic abnormalities (eg, hypoproteinemia) from bingeing, purging, and starvation (eg, heart rate less than 40 beats/min, heart rate greater than 120 beats/min, blood pressure less than 90/60 mm Hg, glucose less than 60 mg/dL [3.3 mmol/L], potassium less than 3 mEq/L [3mmol/L], or inability to maintain core temperature)
- Co-occurring psychiatric symptoms, notably suicidal ideation, self-harm, psychotic depression, or substance use disorder
- Nonresponsive to outpatient treatment (after 3-4 months) and poor motivation to recover
- Demoralization or nonfunctional family
- Denial of severity of abnormal eating behaviors
- Continuous supervision required to prevent purging (eg, vomiting or laxative overuse)

Data from References 3,25,29,31 and 60.

Anorexia Nervosa

Nonpharmacologic Therapy

7 Evidence supports psychotherapy-based treatments have the greatest likelihood of eliciting a response in patients with AN.[30,35,60,65] However, the specific type of psychotherapy that is preferred varies and may include CBT, dialectical behavioral therapy (DBT), focal psychodynamic therapy, acceptance and commitment therapy, behavioral management, specialist supportive clinical management, interpersonal psychotherapy, nutritional counseling, exposure and response prevention, and family therapy.[30,35,37,52,60,65,66] In younger patients, family therapy is the preferred first-line therapy and focuses on re-establishing parental control, promoting wellness, and utilizing other family members for support.[67] Improved outcomes have been seen in patients of a younger age, a shorter duration of illness, a restrictive type AN, being employed, lack of psychiatric co-morbidity, and better social adjustment.[65] Current guidelines suggest at least 6 months of psychotherapy is preferred, though studies of at least 1 year in duration have demonstrated favorable outcomes by reducing relapse rates.[30,60,68] Overall, CBT helps patients overcome distorted thinking, including self-worth as measured by body image, feelings of being fat despite evidence to the contrary, and denial. Additionally CBT teaches how to use strategies besides eating to cope.

Interpersonal psychotherapy focuses on interpersonal relationships and functioning, whereas CBT provides positive reinforcement for weight gain.[38] A combined approach of interpersonal psychotherapy and CBT is a reasonable treatment approach.[37] Initial treatment is directed toward restoring a healthy weight, especially in inpatient settings where target weights are often more rapidly achieved.[37] Many psychiatric symptoms in an acutely ill patient, such as depression and anxiety, diminish or disappear with weight restoration. After medical stability and appropriate weight are reached, therapy can be redirected toward addressing ongoing interpersonal problems, weight maintenance, cognitive restructuring, and skill development for relapse prevention.[30]

Oral refeeding, initially with liquid formulas if necessary, is the most common approach to weight restoration. In severe cases when a patient refuses to eat, nasogastric refeeding is preferred over intravenous bolus dosing in part because it can allow for higher initial caloric intake and has been associated with reductions in length of inpatient hospitalizations and increased rate of weight gain without an increase in complications.[69] Total parenteral nutrition is reserved only for the management of severely malnourished patients and if other refeeding methods fail. The decision to administer total parenteral nutrition must be made carefully, because of the potentially devastating psychological effect on patients who do not wish to gain weight.

Current clinical evidence suggests a controlled weight gain of 0.9 to 1.4 kg (2-3 lb) per week in inpatient settings and 0.2 to 0.5 kg (0.5-1.1 lb) per week in outpatient settings.[3,63,70] Refeeding recommendations vary between younger patients and adults and are considered controversial. An acceptable approach for younger patients is to begin refeeding at 800 to 1,000 cal/day (3,300-4,200 J/day), while others suggest a more aggressive approach.[71] Adults may be considered for refeeding initiation in the range of 1,000 to 1,600 cal/day (4,200-6,700 J/day) (30-40 cal/kg/day [130-170 J/kg/day]) with slow titration (every other day) upward (100-200 cal/day [420-840 J/day]) until they begin to demonstrate sustained weight gain or achieve target weights.[35,60,72] This can require the intake of an additional 3,500 to 7,000 cal (14,600-29,300 J) per week.[60] Slow refeeding has long been considered important to prevent psychological and medical consequences, including the potentially fatal severe electrolyte disturbance that results from insulin surges known as refeeding syndrome. However, too conservative of an approach results in further weight loss early in treatment (unfeeding syndrome), which contributes failure in achieving nutritional recovery goals.[73]

Pharmacologic Therapy

Antidepressants

Studies have examined the role of antidepressants in the treatment of AN, but are limited by small sample sizes and large confidence intervals. Concurrent major depressive disorder has been associated with longer AN associated hospitalizations and fewer patients achieving weight restoring and caloric intake goals.[74] Antidepressants currently have no role in the acute treatment of AN, unless there is another clinical indication present.[25,35,61]

Pharmacotherapy may be ineffective, especially in cases where the patient is below their expected weight. Thus, antidepressants should be initiated only if depression, anxiety, obsessions, or compulsions persist after the target weight is achieved.[25,70] The duration of treatment is unclear, but one study showed benefit in patients treated for 1 year, and current guidelines suggest 9 to 12 months of therapy.[30,35,60,65,68] Antidepressants, along with psychotherapy, have been used to help maintain weight and prevent relapse, but data supporting this are limited. Most clinicians prefer the selective serotonin reuptake inhibitor (SSRI) antidepressants because they are better tolerated and have greater cardiovascular safety than tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs).[30,35,65,68] Because these patients are sensitive to anticholinergic and cardiovascular effects, low starting doses and slow titration toward an effective dose are appropriate if a TCA or MAOI are used. The risk of cardiotoxicity in a malnourished population must not be underestimated, and a baseline electrocardiogram (ECG) should be obtained before initiation of these agents. Chapter 88, "Depressive Disorders," contains a list of common adverse effects seen with antidepressant use.

Fluoxetine is the most widely studied SSRI in AN. Most clinicians initiate at low doses (eg, 20 mg/day), and increase to a maximum of 60 mg/day based on response and tolerability.[72,73,75] Controversy exists regarding when antidepressant therapy should be initiated. Antidepressants may be ineffective during the starvation phase of anorexia, partly due to reduced tryptophan levels. Debate remains as to their effectiveness once weight restoration has occurred. Evidence from a 52-week, randomized, placebo-controlled clinical trial which included fluoxteine doses from 20 to 80 mg/day after weight restoration showed no difference for time to relapse.[76] In addition, the greatest risk of relapse appears to be within the first 60 days after discharge to outpatient care.[77]

Antipsychotics

First- and second-generation antipsychotics have been utilized as a treatment for AN, specifically targeting anxiety and obsessive and paranoid thoughts related to weight gain. First-generation antipsychotics contribute to BMI gains, but provide little benefit overall at reducing other core symptoms, and their associated adverse events outweigh the benefits. Second-generation antipsychotics have provided an additional alternative for treating AN, with reports of improvement in weight gain and reductions in symptoms such as depression, anxiety, and obsessive-compulsiveness. Most of the data are from case reports or small trials in both adolescents and adults using risperidone 0.5 to 2.5 mg daily, olanzapine 2.5 to 10 mg daily, and quetiapine 50 to 800 mg daily.[76,78-82] In addition, an outpatient study examining olanzapine versus placebo, independent of concurrent psychotherapy, demonstrated significant improvement in rate of weight gain and achieved a higher BMI, though there was no difference in obsessive behaviors.[83] Despite these reported benefits, a meta-analytic review of second-generation antipsychotics that included olanzapine, quetiapine, and risperidone did not find significant differences in BMI gains or eating disorder psychometric outcome assessments.[84]

Optimal treatment duration is unknown, as most of the larger studies are less than or equal to 3 months in duration. Chapter 87, "Schizophrenia," contains a list of common adverse effects seen with antipsychotic use.

Miscellaneous Agents

Metoclopramide can be helpful in reducing bloating, early satiety, and abdominal pain commonly found in AN, but it does not affect weight gain.[35] Low-dose, short-acting benzodiazepines (eg, 0.25 mg alprazolam or 0.5 mg lorazepam) given before meals are useful when severe anxiety limits eating.[35] Estrogen replacement has been used, but restoring menses through refeeding is the preferred approach to minimize bone density loss. Supplementation with zinc is also being studied to assist with weight restoration.[65]

Combination Therapy

The combination of psychotherapy and pharmacotherapy, while routinely done in practice, lacks randomized, placebo-controlled, blinded studies to support outcome difference compared to either treatment approach alone. Fluoxetine and olanzapine have each been studied in combination with behavioral or cognitive-behavioral therapy within inpatient and outpatient settings. Only one study that combined a day-hospital program with olanzapine demonstrated significant benefit with weight restoration, achieving the target BMI, and reducing obsessive symptoms.[81]

Bulimia Nervosa

Nonpharmacologic Therapy

Outpatient-based treatment is most often recommended except in extreme cases (see Table e83-2). The nondrug strategies used in BN are similar to those used with AN, and they are equally critical to success. Overall, CBT has the strongest evidence supporting its benefit in managing BN.[30,60,65,85] According to treatment guidelines CBT should consist of 16 to 20 sessions over a 4- to 5-month period.[30,60] Thirty percent to 50% of individuals who receive CBT for BN may be abstinent from binge-eating and purging behaviors by conclusion of the treatment.[86] Interpersonal psychotherapy also plays a role and has a moderate degree of evidence to support its use, but it is considered less effective than CBT.[35] CBT is considered more effective at reducing bingeing and purging episodes than psychoanalytic psychotherapy and also faster at alleviating eating disorder features and general psychopathology. Psychodynamic therapy as well as family-based therapy are also viable options for treatment of adolescents with BN.[86] Nutritional counseling, planned meals, especially regular consumption of evening meals, and self-monitoring can help interrupt the binge–purge cycle.[87] Programs using motivational teaching and guided CBT-based self-help programs which target mechanisms such as dietary restraint and shape and weight concerns have shown promise.[38,85,88-90] When such programs have been combined with medication (eg, fluoxetine), enhanced response has been reported. Online delivery of CBT and web-based aftercare may provide an acceptable treatment alternative for patients who have limited access.[91] Data support the use of 12-step programs, but they should not be used as monotherapy.[25,35] Additional nonpharmacologic strategies may include the promotion of aerobic exercise, yoga, massage therapy, and body awareness therapy.

Pharmacologic Therapy

Antidepressants

⑧ Antidepressants are often used in the acute and maintenance phases of BN adjunctively with nonpharmacologic approaches. Most evidence-based guidelines consistently recommend antidepressants, specifically fluoxetine, in combination with psychotherapy.[93] A wide array of antidepressants, including TCAs, MAOIs, trazodone, serotonin–norepinephrine reuptake inhibitors (SNRIs), bupropion, and SSRIs, have been studied. Additionally, several reviews analyzing this body of literature have been published, although there continues to be limited placebo-controlled, randomized, double-blind clinical studies.[23,61,85,94] Antidepressants are reported to reduce depression, anxiety, obsessions, and impulsive behaviors, such as binge-eating and purging, and improve eating habits, although their impact on body dissatisfaction remains unclear. The presence of comorbid mood disorders is not necessary for a response in patients with BN.

Their benefit appears to be more robust in the acute phase of the illness, as relapse despite continued antidepressant use is common in patients who are in or near remission.[25,63] Antidepressant response usually occurs in 6 to 8 weeks, and reduction in frequency of binge–purge behavior ranges from 0% to 73%.[61] Abstinence rates (eg, elimination of bingeing and purging behaviors) with short-term use range from 0% to 68%. More data are needed to determine the long-term benefits of antidepressants for preventing relapse of bulimia symptoms. One trial evaluating the impact of fluoxetine versus placebo in the maintenance phase showed a better outcome in patients receiving fluoxetine 60 mg daily, although high dropout rates in both groups blurred the overall benefit.[95]

SSRIs are the preferred agents because of their tolerability and because they have been studied in the largest number of patients. Fluoxetine remains the only medication with FDA approval for BN in adults. While it is not approved for pediatric BN, fluoxetine is FDA approved for child and adolescent depression and obsessive-compulsive disorder, making it a reasonable option if pharmacologic treatment of BN is considered in pediatric patients.[96] Efficacy of other SSRI agents is still lacking, but an alternative SSRI may be considered in clinical practice for those not responding to fluoxetine.[94] Tolerability is the primary criterion for selecting an antidepressant in the treatment of BN because of patients' heightened sensitivity to adverse effects and the lack of a clear difference in efficacy between the classes. Even though there is a suggestion that MAOIs produce the most robust effect, the risk of using these medications in impulsive patients limits their use.[63] SNRIs have shown promising results; however, the data supporting their use are limited to case reports. Bupropion, a norepinephrine–dopamine reuptake inhibitor, is contraindicated in patients diagnosed with BN because of the increased risk of seizures seen in patients with an eating disorder.

Before initiating pharmacologic therapy, a careful baseline physical examination, ECG, and laboratory workup are essential. Underlying ECG changes secondary to hypokalemia or bradycardia and atrioventricular block from starvation can be present. There is potential for fatal outcomes secondary to cardiac arrest or suicide. All antidepressants can cause seizures; thus, a careful risk–benefit assessment is warranted if the patient has predisposing factors such as a personal or family history of seizures, cerebrovascular disease, or alcohol or sedative–hypnotic withdrawal.

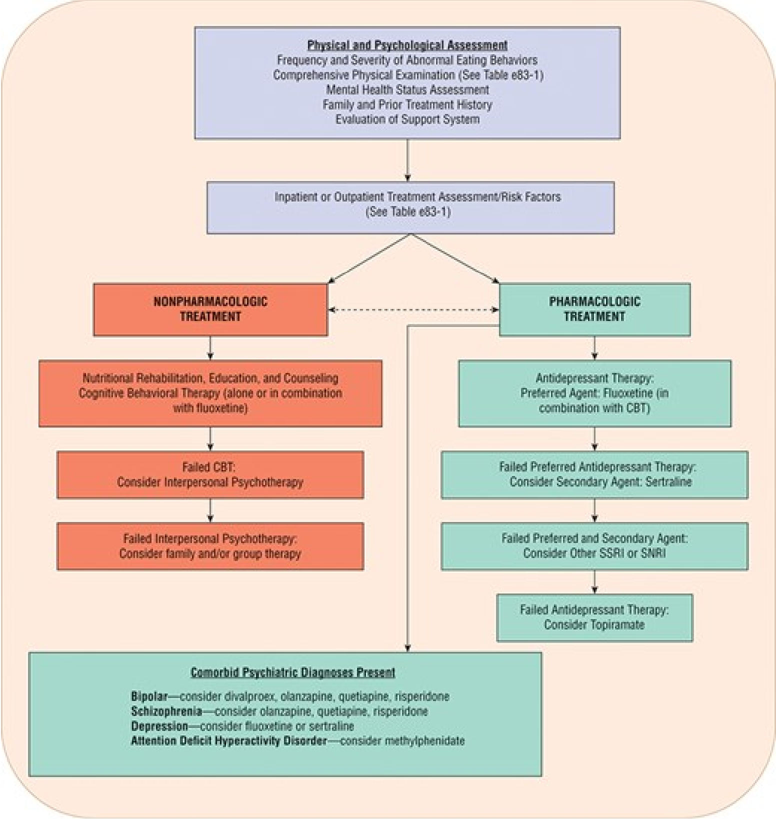
Doses in the treatment of BN are similar to those used for depression, although at the higher end of the range. Chapter 88 includes antidepressant dosing ranges, of note, fluoxetine 60 mg daily can be necessary for response.[97] With all agents, most clinicians initially target the bottom to the middle of the dosing range and increase the dose if there is an inadequate response. Slow titration is needed to allow for tolerance to adverse effects. If TCAs are used, serum concentration monitoring is recommended to ensure that absorption is not compromised by purging.

The time for antidepressant onset of effect in BN is unclear. In the absence of data, the definition of a therapeutic trial from the depression literature (eg, 4-8 weeks at a therapeutic dose) should be used. Response (eg, defined as greater than 60% reduction in binge-eating or vomiting frequency) by week 3 is a positive predictor of eventual treatment response.[98] Because the majority of subjects will not experience a complete remission, and data regarding predictors of response or the impact of switching to another class are not available, clear and specific treatment outcomes should be stated initially.[19]

Optimal duration of treatment after response is poorly defined, although most clinicians treat for 9 months to 1 year and then reevaluate. The evidence is mixed as to whether any early benefit is sustained; hence, the decision to continue treatment should be made based on both initial response and the maintenance of that benefit. If the symptoms return within a few months after antidepressant discontinuation, then the treatment may need to be reinitiated. Figure e83-2 describes criteria for medication use in BN.

FIGURE e83-2

Bulimia nervosa treatment algorithm. (CBT, cognitive behavioral therapy; SNRI, serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor)



Physical and Psychological Assessment
Frequency and Severity of Abnormal Eating Behaviors
Comprehensive Physical Examination (See Table e83-1)
Mental Health Status Assessment
Family and Prior Treatment History
Evaluation of Support System
Inpatient or Outpatient Treatment Assessment/Risk Factors (See Table e83-1)
NONPHARMACOLOGIC TREATMENT
PHARMACOLOGIC TREATMENT
Nutritional Rehabilitation, Education, and Counseling Cognitive Behavioral Therapy (alone or in combination with fluoxetine)
Failed CBT: Consider Interpersonal Psychotherapy
Failed Interpersonal Psychotherapy: Consider family and/or group therapy
Antidepressant Therapy: Preferred Agent: Fluoxetine (in combination with CBT)
Failed Preferred Antidepressant Therapy: Consider Secondary Agent: Sertraline
Failed Preferred and Secondary Agent: Consider Other SSRI or SNRI
Failed Antidepressant Therapy: Consider Topiramate
Comorbid Psychiatric Diagnoses Present
Bipolar—consider divalproex, olanzapine, quetiapine, risperidone
Schizophrenia—consider olanzapine, quetiapine, risperidone
Depression—consider fluoxetine or sertraline
Attention Deficit Hyperactivity Disorder—consider methylphenidate

Miscellaneous Agents

Due to lack of evidence demonstrating their benefit, lithium and traditional antiseizure medications are reserved for patients diagnosed with BN and comorbid bipolar disorder.[35,99] Randomized, placebo-controlled trials with topiramate have demonstrated reduced binge/purge frequency and weight loss versus placebo, although adverse effects including cognitive impairment and paresthesia may hinder medication adherence.[100,101] Low-dose benzodiazepines before meals can help reduce anxiety associated with refeeding, although long-term use is not warranted because of the risk of dependence. One double-blind trial with ondansetron has shown benefit, but there are insufficient data to recommend a specific role for this agent.[102] One small, open-label, pilot study of zonisamide showed it to be effective in BN, but further data are needed to confirm its role in treatment.[103] Data are conflicting on the opiate antagonist naltrexone with only modest improvement seen at high doses, but it is not recommended due to risk of elevated hepatic transaminases.[78] Antipsychotics and appetite suppressants do not play a role in managing core symptoms of BN.[25]

Combination Therapy

The combination of pharmacologic and nonpharmacologic measures appears to produce the best chance for positive outcomes for patients with BN. However, a recent review of randomized controlled trials suggested no added benefit.[60,104] Antidepressants, specifically SSRIs, are the medications of choice in patients diagnosed with BN, whereas other medications are reserved for patients with comorbid psychiatric conditions. Only in unusual circumstances should patients be treated with antidepressants alone. The greatest benefit of SSRI use is during the acute phase of treatment, whereas data are mixed regarding their role in the prevention of relapse.

Binge-Eating Disorder

Nonpharmacologic Therapy

CBT is universally accepted as the nonpharmacologic treatment intervention of choice, specifically aimed at reducing the number binge-eating episodes that results in a remission rate of approximately 50%.[105,106] Evidence supports individual, group, and guided self-help are efficacious. In general, interpersonal psychotherapy (IPT) has demonstrated comparable efficacy to CBT at 1-, 2-, and 5-year follow-up reviews, with DBT and mindfulness also being appropriate psychotherapy treatment interventions, though not considered first-line.[107,108] These interventions have been shown to improve long-term remission rates.[109] Improvements in impulse control and cue reactivity should be included as a target of psychotherapeutic interventions.[110,111] Behavioral weight loss programs typically produce a 5% to 10% weight loss which is often regained in the subsequent 1 to 2 years.[102] Sustained weight loss has been more favorably associated with CBT.[105,109,112] Physical activity used in conjunction with CBT and a dietary program has resulted in improvement of both binge episodes and BMI. Other innovative treatments of interest include cue-exposure therapy, virtual reality, tele-delivery of services, and the ketogenic diet.[110,113]

Pharmacologic Therapy

⑨ Lisdexamfetamine, antidepressants, and antiseizure medications are the pharmacologic agents most extensively studied in BED. Antidepressants have demonstrated efficacy as monotherapy at reducing binge-eating and improving depressed mood during the acute phases of the illness compared with placebo.[30,78,111,114-116] The SSRIs citalopram (20-60 mg), escitalopram (10-30 mg), fluvoxamine (up to 200 mg), fluoxetine (40-80 mg), and sertraline (100-200 mg) are associated with improvement in BED-related symptoms.[111,114,115,117] This includes a reduction in binge frequency, improved mood symptoms, and reduced obsessive-compulsive symptoms, though not all studies have included each of these outcome measures in their methodology.[117] The majority of the data are with antidepressant doses, and interestingly, the combination of antidepressants with CBT has not borne out improved outcomes in most studies.[105,107-109] Vortioxetine, with a target dose of 20 mg daily, failed to separate from placebo in a recent clinical trial, although a naturalistic study (mean dose 15.8 mg daily) showed improvement in BED symptoms in participants with comorbid MDD.[118,119]

Atomoxetine (40-120 mg) and venlafaxine (75-300 mg) have evidence to support improvement in BED symptoms with reduction in binge frequency, reduced BMI, weight loss, and improved mood symptoms.[117] Duloxetine has also been studied in comorbid depression with reductions in binge-eating and depressive symptoms.[120] Although bupropion has not shown improvement in BED outcomes with the exception of two case reports, naltrexone/bupropion had resulted in Binge Eating Scale score improvement and depressive symptoms with further research warranted.[121,122]

Lisdexamfetamine is a prodrug of dextroamphetamine and is FDA approved for the treatment of moderate to severe BED (30 mg initially and titrated to 50-70 mg daily). Clinical trials demonstrated reductions in numbers of binge days per week, a greater percentage of patients with global clinical improvement, a higher percentage achieving a 4-week cessation of binge episodes, functional outcomes, and improvement in obsessive-compulsive psychometric measures.[123,124] The aforementioned outcomes are supported out to 52 weeks.[125-127] An additional stimulant, methylphenidate (18-72 mg daily), has been compared to CBT with similar remission rates.[122]

Topiramate (25-300 mg daily) reduced binge frequency, body weight, and BMI, and remission rates were higher when combined with CBT.[128] Combination of phentermine/topiramate was effective for weight loss and improvement in binge-episode frequency and psychopathology in two open-label studies and a small clinical trial.[129] Zonisamide (100-600 mg/day) alone and in combination with CBT over the course of 16-week and 1-year studies demonstrated efficacy at reducing binge-eating and weight loss; however, there were high dropout rates due to intolerability.[94]

Orlistat (120 mg given three times daily), along with calorie-restricted diet, produced weight reduction in obese patients with BED.[130] Other medications used to treat obesity are being explored as possible treatment options. Liraglutide specifically has demonstrated improvement in binge eating, but this patient population was not formally diagnosed with BED.[78]

Current literature suggests that lisdexamfetamine, SSRIs, topiramate, and dasotraline (dopamine/norepinephrine reuptake inhibitor) hold the most promise in the short term, but long-term data is lacking.

Combination Therapy

The combination of pharmacologic and nonpharmacologic measures for BED has been examined in 12 randomized clinical trials with no identified benefit. Two randomized clinical trials have added antiseizure medications to CBT (zonisamide and topiramate) with significantly greater reductions in select binge-eating outcomes and BMI than CBT alone.[104]

EVALUATION OF THERAPEUTIC OUTCOMES

Eating Disorder Guideline Summary

Formalized treatment guidelines are available to assist in the management of eating disorders, specifically for AN, BN, and BED.[30,35,60,117,131] Although guidelines are an important tool to aid in the decision-making process in developing treatment and management strategies, it is important to note variation in release dates of the various guidelines as this affects the information able to be included at the time of publication.

Anorexia Nervosa

A combination of subjective and objective measures is used to assess response in patients with AN. A reduction in the frequency and severity of abnormal eating habits, normalized exercise patterns and laboratory tests, and a sustained weight close to age-matched non-affected individuals are key indicators of response. A diary recording exercise frequency, menses, food intake, patterns of eating, and associated feelings while eating is a useful tool to track progress, especially in the outpatient setting. Weekly weigh-ins on the same scale, preferably at a clinician's office, help monitor progress early in treatment and reduce the focus on weight and anxiety caused by the variability found among different scales. Follow-up laboratory tests and ECGs are not part of routine monitoring unless the patient is restricting food intake, is purging, or continues to lose weight despite treatment. Inpatients require daily assessment of weight and caloric intake, vital signs, and urine output because of the severity of their illness. This may include monitoring of bathroom privileges early in their care. A healthy weight gain of not more than 0.2 to 0.5 kg (0.4-1.1 lb) per week, toward a goal of 90% to 95% of normal weight or a BMI greater than 18.5 kg/m^2 is a critical sign of treatment success. A patient's use of coping skills and contingencies for dealing with stress, other than manipulating food consumption, also should be assessed. Antidepressants can assist in alleviation of persistent depression, anxiety, and obsessions, after weight restoration. Improvement in mood is expected to occur within 8 weeks. Patients receiving TCAs should be evaluated for dry mouth, constipation, hypotension, and sedation and patients receiving SSRIs should be monitored for agitation, medication-induced anorexia, nausea, weight loss, and insomnia. The decision to use long-term medication must be based on specific and sustained improvement in the target symptoms, balanced against adverse effects.

Recent research has focused on quality of life as a primary outcome measure compared to targeting specific symptoms of AN as quality of life is generally lower in individuals with a history or clinical presence of an eating disorder. Preliminary findings, however, suggest that improvement in quality of life is in part dependent on symptom improvement and weight gain, thus weight gain and behavioral change should remain the focus of treatment.

Bulimia Nervosa

Individualized treatment and monitoring plans begin with a thorough assessment describing the baseline frequency and severity of treatment-responsive target symptoms and other associated findings. This must be comprehensive, as a patient can hide their illness by shifting from one type of behavior to another (eg, exercise to purging).

This comprehensive assessment should include a description of psychiatric symptoms, physical findings, frequency and severity of binge–purge episodes, laxative and ipecac use, exercise patterns, and laboratory and ECG abnormalities. Interpersonal and relationship problems should also be evaluated. Some findings indicating a more chronic course of illness, such as salivary gland inflammation and erosion of dental enamel, can take months to reverse or might never normalize, making them poor indicators of early treatment response. Data describing a patient's baseline level of functioning and previous response to treatment should be used to set goals in the current treatment plan.

Antidepressant response usually occurs within 4 to 8 weeks after treatment onset. If response does not occur, binge–purge behavior should be considered as a factor potentially contributing to medication malabsorption. If this behavior is not present, then every attempt should be made to maximize the dose. TCA serum concentration monitoring should be done periodically (eg, every 3 to 6 months if a patient is responding and tolerating the medication, or more frequently if clinically indicated). Evaluation of adverse medication effects should be part of the monitoring plan. If the patient responds, they should be followed for 6 to 12 months, and then reassessed for the need for ongoing medication. If they relapse after medication discontinuation, then pharmacotherapy should be restarted. There is an increased risk of suicidality associated with antidepressant use in major depression; thus suicidality should be assessed following antidepressant initiation, especially early in therapy. Chapter 88 includes further details and more comprehensive information related to antidepressant use.

Patients receiving eating disorder treatment on an outpatient basis present a particular challenge to clinicians, as impulsivity associated with BN can increase the risk for suicide. To reduce the risk of medication overdoses, prescriptions should be limited to small supplies. In addition, clinicians should be alert to persons who make large or frequent purchases of laxatives or ipecac syrup, as this is an indicator of possible purging behaviors.

Binge-Eating Disorder

Similar to BN, the frequency and severity of binge episodes should be monitored. In addition, psychiatric symptoms, physical findings, and interpersonal problems should be assessed. Patients with BED are at a higher risk of suicide (suicide attempt prevalence 22.9%) and thus close monitoring of mood should be included in the treatment plan.[132,133]

Evaluation of adverse effects should be monitored as indicated during discussion of AN and BN. If weight loss is being pursued, all appropriate measures such as weight, calculated BMI, and waist circumference are indicated. Please refer to Chapter 167, for further details and more comprehensive information related to treatment of obesity. Metabolic parameters should be periodically assessed and monitored. There is a relative paucity of literature to guide length of treatment, although recommendations for BN could be extrapolated to BED.

CONCLUSION

The treatment of AN is complex and involves preferred strategies of psychotherapy that may include CBT, DBT, and nutritional counseling among several others. Pharmacologic strategies are not aimed at core AN symptom reduction, but rather concurrent mental illness that often accompanies AN. This can include the use of both antidepressants and antipsychotics. Antidepressants have not been shown to be clinically meaningful for core AN symptoms, but may be appropriate with co-occurring depression. Antipsychotics have also been shown to aide in managing anxiety, paranoia, and obsessions associated with weight gain, while also helping to improve patient BMIs.

Assessment of BN patients include frequency and severity of binge–purge episodes, laxative and ipecac use, exercise patterns, physical and laboratory findings, and other psychiatric symptoms. Cognitive behavioral therapy is the nonpharmacologic treatment of choice. Antidepressants, particularly SSRIs, are used in the acute and maintenance phases of BN adjunctively with nonpharmacologic approaches. Antidepressant response usually occurs in 6 to 8 weeks. Monitoring for response as well as adverse effects is a critical part of the plan.

The treatment of BED necessitates a holistic approach including nonpharmacologic therapy such as CBT along with nutritional guidance and weight loss, if applicable. Lisdexamfetamine is the sole FDA-approved agent for treatment of moderate to severe BED, although evidence exists for antidepressants and antiseizure medications, namely topiramate. As with all eating disorders, monitoring for adverse effects and ongoing BED symptoms should be assessed regularly.

ABBREVIATIONS

5-HIAA	5-hydroxyindoleacetic acid
5-HT	serotonin
5-HTTLPR, SLC6A4	serotonin transporter
AN	anorexia nervosa
BDNF	brain-derived neurotrophic factor
BED	binge-eating disorder
BMI	body mass index
BN	bulimia nervosa

CBT	cognitive behavioral therapy
CNS	central nervous system
CSF	cerebrospinal fluid
CT	computerized tomography
DBT	dialectical behavior therapy
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition
ECG	electrocardiogram
EEG	electroencephalogram
ESRI	estrogen receptor I gene
GI	gastrointestinal
IPT	interpersonal therapy
MAOI	monoamine oxidase inhibitor
MRI	magnetic resonance imaging
NES	night eating syndrome
OCD	obsessive-compulsive disorder
SNRI	serotonin–norepinephrine reuptake inhibitor
SSRI	selective serotonin reuptake inhibitor
TCA	tricyclic antidepressant

SELF-ASSESSMENT QUESTIONS

1. Suspected deficiencies of serotonin have commonly been linked to anorexia nervosa, primarily thought to be the result of a reduction in the intake of which of the following amino acids?

   A. Glycine

   B. Tyrosine

   C. Glutamine

   D. Tryptophan

2. Which of the following is/are required when considering a diagnosis of anorexia nervosa?

   A. Restriction of energy intake leading to low body weight

B. Undue influence of body shape on self-evaluation

C. Behavior that interferes with weight gain

D. All of the above

3. A 16-year-old female is being evaluated for a possible diagnosis of anorexia nervosa. Their history reveals that they have a sister diagnosed with anorexia nervosa, their father is diagnosed and treated for bipolar disorder, Type 1, and they have been treated for asthma since a young age. They have also been regularly using cannabis and alcohol since the age of 13. Which of the following are considered positive risk factors for developing anorexia nervosa?

A. Substance use disorder

B. Sibling with anorexia nervosa

C. Presence of a mood disorder

D. All of the above

4. A 17-year-old with anorexia nervosa is currently undergoing caloric restoration at a rate 800 cal/day (3,300 J/day). The physician is most worried about:

A. Refeeding syndrome

B. Cardiac arrhythmia

C. Unfeeding syndrome

D. Renal failure

5. The second-generation antipsychotic olanzapine has demonstrated effectiveness in combination with day hospital treatment at increasing weight gain and also as treatment alone to improve BMI. The results of a recent meta-analysis examining the impact of olanzapine, quetiapine, and risperidone discovered which of the following?

A. Olanazpine and quetiapine produced significant BMI gains

B. Risperidone produced significant BMI gains, but had higher rates of EPS

C. Olanzapine, quetiapine, and risperidone increased weight gain and BMI

D. Olanzapine, quetiapine, and risperidone did not significantly impact BMI

6. Which of the following lacks maladaptive compensatory mechanisms such as over-exercise or purging?

A. Anorexia nervosa

B. Bulimia nervosa

C. Binge-eating disorder

D. None of the above

7. Which of the following pairs share the core feature of binge-eating?

A. Binge-eating disorder and anorexia nervosa

B. Binge-eating disorder and bulimia nervosa

C. Anorexia nervosa and bulimia nervosa

D. Anorexia nervosa and night eating syndrome

8. In patients with binge-eating disorder, which of the following conditions are they at an increased risk of developing?

A. Refeeding syndrome

B. Diabetes mellitus type 2

C. Osteopenia

D. Dental caries

9. A 23-year-old patient presents to your outpatient clinic. They report a recent diagnosis of binge-eating disorder and is interested in what types of therapy might be most helpful. They denies any previous therapy. What would you recommend?

A. Cognitive behavioral therapy (CBT)

B. DBT (dialectic behavioral therapy)

C. Mindfulness

D. Behavioral weight loss (BWL)

10. A 30-year-old patient is picking up their prescriptions at your community pharmacy. Upon review, the patient confirms that they are picking up their monthly oral contraceptives, duloxetine capsules 60 mg by mouth once daily, sumatriptan tablets 100 mg as needed for migraines, and tramadol tablets 50 mg every 6 hours as needed for pain. They reports they would like to start a medication for their "secret binges," which their physician has diagnosed as binge-eating disorder. Which of the following options would you recommend?

A. Lisdexamfetamine

B. Sertraline

C. Bupropion

D. Topiramate

11. Nonpharmacologic strategies in the treatment of BN are critical to success. Which nondrug strategy offers the most robust evidence supporting its benefit?

A. Sixteen to 20 sessions of cognitive behavioral therapy over 4 to 5 months

B. Family-based therapy

C. Interpersonal psychotherapy

D. Motivational teaching and self-help guides

12. JS is a 22-year-old female diagnosed with bulimia nervosa. Which characteristic below does not fit with the diagnostic criteria for BN?

A. Average height and weight at presentation but has periods where she fluctuates between overweight and underweight

B. Presenting symptoms of anxiety, history of substance use, and difficulty with personal relationships

C. Several times a month she eats excessively and feels very guilty about it afterward

D. Lack of concern over her body image

13. All of the following are acceptable pharmacologic treatments for bulimia nervosa, except:

    A. Fluoxetine 60 mg/day

    B. Phenelzine 90 mg/day

    C. Bupropion 300 mg/day

    D. Desipramine 150 mg/day

14. CB is a 24-year-old who presents with a 3-month history of symptoms including depressed mood, poor sleep, and weight loss due to lack of appetite and fear that their food may be tainted with poison. What characteristics should be present to support a differential diagnosis of eating disorder?

    A. Disturbed body image

    B. Overriding drive for thinness

    C. Increased energy directed at losing weight

    D. All of the above

15. Patients diagnosed with BN lack control over their eating and participate in recurrent compensatory behavior to prevent weight gain. The non-purging subtype engages in behaviors including all of the following, except:

    A. Self-induced vomiting

    B. Overuse of laxatives, diuretics, or enemas

    C. Strict dieting or fasting

    D. Excessive exercise

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Serotonin, norepinephrine, and dopamine have been studied extensively with well-described roles in controlling eating behaviors. Special emphasis has been placed on the role of serotonin (5-HT), specifically noting reduced cerebrospinal fluid (CSF) basal concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the principal metabolite of 5-HT, as well as increased binding of 5-HT1A receptors and reduced binding of 5-HT2A receptors in different regions within the central nervous system (CNS). Reduced dietary intake of tryptophan-containing leads to reduced levels of tryptophan, a requirement for the development of 5-HT (see "Pathophysiology" section).

2. **D.** The presentation of AN includes a recent period of weight loss as well as associated behaviors to promote this such as vomiting, limiting food intake, and excessive exercise. Current diagnostic criteria for AN include the restriction of energy intake relative to requirements that leads to low body weight contextually as it relates to age, sex, developmental trajectory, and physical health. The *DSM-5* further classifies AN as restricting type in which patients restrict food intake with no binge-eating or purging behavior over the past 3 months, or binge-eating/purging type, in which patients regularly participate in bingeing or purging over the prior 3 months. The severity of AN is based upon body mass index (BMI) in adults and BMI percentiles in children and adolescents. Comorbid psychiatric conditions, such as major depression, are frequent but should initially be considered secondary to starvation and not a true mood disorder (see "Clinical Presentation" section).

3. **D.** Specific risk factors for AN include being female, having a sibling with AN, the presence of mood disorders in family members, and comorbid anxiety, personality, or substance use disorders (see "Clinical Presentation" section).

4. **C.** Current clinical evidence suggests a controlled weight gain of 0.9 to 1.4 kg (2-3 lb) per week in inpatient settings and 0.2 to 0.5 kg (0.5-1.1 lb) per week in outpatient settings. Refeeding recommendations vary between younger patients and adults and are considered controversial. An acceptable

approach for younger patients is to begin refeeding at 800 to 1,000 cal/day (3,300-4,200 J/day), while others suggest a more aggressive approach.[71] Adults may be considered for refeeding initiation in the range of 1,000 to 1,600 cal/day (4200-6700 J/day) (30-40 cal/kg/day [130-170 J/kg/day]) with slow titration (every other day) upward (100-200 cal/day [420-840 J/day]) until they begin to demonstrate sustained weight gain or achieve target weights. This can require the intake of an additional 3,500 to 7,000 cal (14,600-29,300 J) per week. Slow refeeding has long been considered important to prevent psychological and medical consequences, including the severe electrolyte disturbance that results from insulin surges known as refeeding syndrome, which can result in death. A criticism is that too conservative of an approach results in further weight loss early in treatment (unfeeding syndrome), contributing to a failure to achieve nutritional recovery goals (See "Treatment" section).

5. **D.** Olanzapine in combination with day hospital treatment has been shown to be more effective than day hospital treatment alone in achieving greater weight gain and reducing obsessive symptoms. In addition, an outpatient study examining olanzapine versus placebo, independent of concurrent psychotherapy, demonstrated significant improvement in BMI. Despite these reported benefits, a meta-analytic review of second-generation antipsychotics that included olanzapine, quetiapine, and risperidone did not find significant differences in BMI gains or eating disorder psychometric outcome assessments (see "Treatment" section).

6. **C.** The symptoms of AN can include purging, restricting caloric intake, and overexercise. BN includes purging behaviors. Binge-eating disorder (BED) results in no maladaptive behaviors (see "Clinical Presentation" section).

7. **B.** Binge-eating is not a core feature of AN but is a subtype. Night-eating syndrome can result in excessive food consumption, although since that option is paired with AN, it is not the correct choice. BED and BN share binge-eating as a core diagnostic criterion (see "Clinical Presentation" section).

8. **B.** Refeeding syndrome is associated with caloric restoration in anorexia nervosa. Osteopenia is a potential long-term complication of suppressed estrogen associated with starvation seen in anorexia nervosa. Dental caries can be seen in patients with frequent purging. As patients with binge-eating disorder may be overweight or obese, this increases the risk of diabetes mellitus type 2 (see "Medical Complications of Eating Disorders" section).

9. **A.** For the treatment of binge-eating disorder, DBT, BWL, and mindfulness are not considered first-line (see Fig. e83-2).

10. **D.** The patient is currently on three serotonergic medications: duloxetine, sumatriptan, and tramadol (although it is now generally accepted that triptans do not increase the risk of serotonin syndrome). Lisdexamfetamine may also increase the already elevated risk of serotonin syndrome. In addition, there is a drug-drug interaction between lisdexamfetamine and duloxetine mediated through CYP2D6. Sertraline is a selective serotonin reuptake inhibitor which would also increase risk of serotonin syndrome. Evidence for bupropion in binge-eating disorder is limited to case reports. Topiramate has evidence to support a reduction in binge frequency and body weight with increased remission rates. The patient should be educated on the risk of fetal harm with use of topiramate if they become pregnant (see Fig. e83-2).

11. **A.** Only CBT has the strongest evidence supporting its benefit in managing BN. Current treatment guidelines suggest that CBT should consist of 16 to 20 sessions over a 4- to 5-month period. Thirty percent to 50% of individuals who receive CBT for BN may be abstinent from binge-eating and purging behaviors by conclusion of the treatment. Interpersonal psychotherapy also plays a role and has a moderate degree of evidence to support its use, but it is considered less effective than CBT. Psychodynamic therapy as well as family-based therapy is also viable options for treatment of adolescents with BN. Programs using motivational teaching and self-help guides based on CBT have shown promise (see Fig. e83-2).

12. **D.** The general clinical presentation of BN includes presence of binge episodes that only stop when abdominal pain emerges, purging occurs, or the episode is interrupted by another person; a pattern of severe dieting following by further binge-eating; and concern about body image, although this does not have the excessive drive for thinness characteristic of AN (see "Clinical Presentation" section).

13. **C.** Selective serotonin reuptake inhibitors are the preferred agents because of their tolerability and because they have been studied in the largest number of patients. Fluoxetine remains the only medication with FDA approval for BN. Efficacy of other SSRI agents is still lacking, but an alternative SSRI may be considered in clinical practice for patients who do not respond to fluoxetine.[94] Tolerability is the primary criterion for selecting an antidepressant in the treatment of BN because of patients' heightened sensitivity to adverse effects and the lack of a clear difference in efficacy between the classes. Even though there is a suggestion that MAOIs produce the most robust effect, the risk of using these medications in impulsive patients limits their use.[63] Selective norepinephrine reuptake inhibitors have shown promising results; however, the data supporting their use are limited to case reports. Bupropion, a norepinephrine–dopamine reuptake inhibitor, is contraindicated in patients diagnosed with BN because of the increased risk of seizures seen in patients with an eating disorder (see "Treatment" section).

14. **D.** Eating abnormalities can be a component of or share similar symptoms with psychiatric disorders including depression, obsessive-compulsive disorder, and schizophrenia, thus they should be part of the differential diagnoses of eating disorders. The salient differences are the overriding drive for thinness, disturbed body image, increased energy directed at losing weight, and binge-eating episodes that are relatively specific for eating disorders (see "Clinical Presentation" section).

15. **A.** To meet the *DSM-5* criteria, the binges and compensatory behaviors must occur on average at least once weekly for 3 months. Bulimia nervosa can further be differentiated by purging type (regularly engages in self-induced vomiting or the misuse of laxatives, diuretics, or enemas) or non-purging type (uses other inappropriate compensatory behaviors, such as fasting or excessive exercise, but does not engage in purging activities) (see "Clinical Presentation" section).

Chapter e84: Introduction to Substance Use Disorders

Jessica L. Moreno; Patrick Leffers; Vicki L. Ellingrod

KEY CONCEPTS

KEY CONCEPTS

① Substance use disorders (SUDs), including those pertaining to prescription medications, affect the health and well-being of millions of Americans.

② Patients with SUDs are treated in all healthcare settings.

③ The use of prescription medications other than as prescribed, alone is estimated to cost more than 750 billion dollars annually.

④ There are several national efforts ongoing to monitor substance use trends in adults and children.

⑤ The etiology for SUDs is unknown, as there is no way to predict why some individuals exposed to substances develop a SUD, while others may not. It is felt that SUDs occur when some patients with genetic, psychological, and environmental risk factors are exposed to certain substances.

⑥ The *DSM-5* has established nine types of substance-related disorders including alcohol, cannabis, hallucinogens, inhalants, opioids, sedatives/hypnotics/anxiolytics, stimulants (ie, cocaine, amphetamine substances), tobacco, and caffeine.

⑦ The diagnosis of SUD is based on a set of behaviors related to that substance which fall into four categories including impaired control, social impairment, risky use, and pharmacological indicators.

⑧ The current *DSM-5* stratifies substance-related disorders into two groups: SUDs and substance-induced disorders (eg, intoxication, withdrawal, or medication-induced mental issues).[1]

⑨ The American Society of Addiction Medicine (ASAM) has endorsed recommendations of the Descriptive and Diagnostic Terminology Action Group (DDTAG) to clarify SUD-related terms.

⑩ Validated scales and screening tools provide objective measures of SUDs and are often used in research and clinical settings.

⑪ Treatment of SUDs focuses on a holistic biopsychosocial approach, to provide a recovery that allows the patient to live a full life as they manage symptoms and decrease risk of relapse.

⑫ Terminology surrounding SUDs is evolving. All healthcare providers should strive to use terms and language that are patient-oriented, medically precise, and without stigma.

Applying the Pharmacists' Patient Care Process to Patients with Substance Use Disorder (SUD)

This image shows The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The five fundamental steps are to collect, assess, plan, implement, and follow-up.

This process outlines a comprehensive approach for pharmacists providing patient care services.

Collect

Objective data

- Patient demographics (eg, age, sex, race/ethnicity, pregnancy status)
- Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight
- Prescription drug monitoring program (PDMP) data
- Laboratory tests (eg, urine, blood, hair, or oral fluid drug testing, pregnancy test, liver function tests [LFTs], serum creatinine [SCr], screening for tuberculosis, hepatitis B and C serology, human immunodeficiency virus [HIV] serology)

Medication history

- Current medications (eg, herbal products, dietary supplements, over-the-counter [OTC] medications, and prescription medications)
- Known medication allergies or intolerances

Past medical/psychiatric history

- Past or current co-occurring illnesses (physical and psychiatric), injuries, surgeries, and hospitalizations

- General state of current physical and mental health (eg, good, fair, poor, concern for suicidal ideation)
- Substance use history (eg, tobacco, ethanol, prescription medications taken other than as prescribed, cannabis, heroin/fentanyl, cocaine/crack, methamphetamine, hallucinogens, inhalants)
- Problems resulting from substance use
- Childhood or adolescent abuse (emotional, sexual, physical, verbal)

Social and environmental history

- Living environment and transportation resources
- Education level completed and current employment status
- Current support systems (eg, family, friends, group therapy)
- Family history of SUD (eg, parents, siblings, partners)
- Participation in high-risk activities for contracting HIV or other sexually transmitted infections (STIs)

Assess

Signs and risk factors for SUD

- Dental caries, perforated septum, skin abscesses, needle track marks, swollen extremities
- Withdrawal symptoms
  - Tobacco (irritability, anxiety, difficulty concentrating, increased appetite, restlessness, depressed mood, insomnia)
  - Opioids (Goose bumps, nausea/vomiting/diarrhea, abdominal cramps, tearing, runny nose, yawning, restlessness, bone/joint/muscle aches, diaphoresis, tachycardia, anxiety)
  - Alcohol/sedative hypnotics (tremor, anxiety, agitation, headache, nausea, diaphoresis, pulse greater than 100 bpm, sensory disturbances [auditory, tactile, visual], seizures)
  - Stimulants (dysphoric mood, fatigue, vivid unpleasant dreams, insomnia or hypersomnia, increased appetite, psychomotor slowing/agitation)
  - Cannabis (irritability/aggression, anxiety, restlessness, sleep disruption, reduced appetite, depressed mood, abdominal pain, tremors, sweating, fever, chills, headache)
- Symptoms of intoxication
  - Opioids (euphoria, apathy, psychomotor slowing/agitation, impaired judgment, pupillary constriction, drowsiness, slurred speech, impaired attention/memory)
  - Alcohol (slurred speech, incoordination, unsteady gait, impaired attention/memory, mood lability, impaired judgment)
  - Stimulants (euphoria, hypervigilance, interpersonal sensitivity, anxiety, tension/anger, stereotypic movements, impaired judgment, pupillary dilation, autonomic instability (tachycardia or bradycardia, elevated or lowered BP, diaphoresis or chills), nausea/vomiting, psychomotor agitation, seizures, dyskinesias, dystonias)
  - Cannabis (incoordination, euphoria, anxiety, sensation of slowed time, impaired judgment, social withdrawal, increased appetite, dry mouth, tachycardia)

  - Hallucinogens (impaired judgment, paranoia, ideas of reference, depersonalization, derealization, hallucinations, synesthesia, pupillary dilation, tachycardia, diaphoresis, palpitations, blurred vision, tremors, incoordination)
- Psychiatric and Behavioral
  - Depression, anxiety, low self-worth, mental health disorders, feelings of hopelessness or loss of control, resentment
  - Conduct disorders, impulsivity, alienation from others, involvement with the criminal legal system
- Risk stratification
  - Assess patients for substance use, and SUD.
  - Screening tools and symptom surveys may aid in determining SUD risk (eg, Pain Medication Questionnaire, Opioid Risk Tool, Current Opioid Misuse Measure), opioid withdrawal (eg, Clinical Opioid Withdrawal Scale, Objective Opioid Withdrawal Scale), alcohol use disorder (alcohol use disorder identification test), and respiratory depression (Risk Index for Overdose or Serious Opioid-Induced Respiratory Depression)
- Evaluate patient readiness for recovery using motivational interviewing
  - Highlight consequences that may motivate positive change
  - Identify patients' reasons to start treatment (relationships, quality of life, self)
  - Determine the patients' preferred treatment setting (eg, opioid treatment programs, outpatient office visits with a prescriber)
  - Discuss potential barriers for patient access to treatment for SUD, mental health support, and laboratory tests for monitoring

Plan

- Engage the patient in shared decision making regarding the risks and benefits of each treatment
- Design a medication therapy regimen if applicable (eg, specific medication(s), dose, route, frequency, and anticipated duration of therapy)
- Communicate monitoring parameters including efficacy (eg, cravings, use, and withdrawal symptoms) and safety (eg, drug interactions, side effects); frequency and timing of follow-up
- Educate patients about their diagnosis, medication, and expectations (eg, purpose of treatment, possible side effects, importance of proper storage of medication, naloxone education if applicable, risk of overdose with discontinuation of treatment and return to use, notify other providers they are on a new medication)
- Refer patient to other providers when appropriate (eg, behavioral health specialist, social worker)

Implement

- Review all elements of treatment plan with the patient and their support system (friends, family, significant others)
- Continue to engage the patient with motivational interviewing, establish patient centered goals and identify healthy coping strategies
- Provide home naloxone device and complete proper education with patient and their support system
- Schedule patient follow-up visit

Follow-Up: Monitor and Evaluate

- Reevaluate medication therapy for safety (ie, adverse medication effects) and effectiveness (eg, effects on cravings and ongoing substance use) daily to weekly until stable

- Labs/tests: liver function tests, serum creatinine, drug testing with patient consent, electrocardiogram (for patients on methadone)
- For opioid agonists and partial agonists
    - Initiate individualized dosing focused on improving symptoms of withdrawal without over-sedation
    - Titrate dosing over days to weeks to target cravings and blunt the euphoric responses from self-administered nonprescribed opioids
- Assess patient for changes in health (eg, pregnancy, pulmonary disease, hepatitis) and medications (prescribed, OTC, or herbals)

INTRODUCTION

Psychoactive substance use dates back to prehistoric times where humans in the Neolithic era (8,500-4,000 BC) were found to use mood altering plants and fruits.[2] Thus, SUDs are not new; however, the types of substance used have evolved from the naturally occurring sources such as opium, alcohol, cannabis, peyote, psychedelic mushrooms, and coca leaves to synthetic or manufactured products. In fact, illicitly manufactured fentanyl (IMF) products fueled the third phase of the overdose crisis and have contributed to unprecedented overdose deaths across the United States.[3]

① Society's views on what are considered non-socially acceptable drugs have also changed with time. Alcohol, nicotine, and caffeine are three prime examples substances considered by most to be socially acceptable. Much of this is due to a prohibitionist approach the United States has taken against most other drugs, which cannot be separated from the county's sordid past with racism such that drugs more often used by people of color have been, and continue to be, more heavily policed.[4] Even though alcohol and nicotine tend to be more socially acceptable substances, their use imposes an enormous social and economic cost on our society. The World Health Organization (WHO) estimates that in 2016, there were more than 3 million deaths worldwide attributed alcohol consumption with the majority being males. Additionally, it is estimated that more than 2.4 million individuals with an alcohol use disorder (AUD) also have another SUD.[5] In recent years, many states have enacted legislation to allow medical and, sometimes, recreational use of cannabis; however, up to 30% of those who use cannabis may develop a use disorder, and this risk is seven times higher in those who start using before the age of 18 years.[6,7] Additionally, the use of psychedelic/hallucinogenic substances is now becoming more mainstream as research into their therapeutic use is growing. Currently research on the use of ketamine, lysergic acid diethylamide (LSD), and psilocybin mushrooms are ongoing for the treatment of depression and posttraumatic stress disorder (Chapter 88).[8] While there has been an increasing variety of legal substances available in recent history, these legal substances tend to have lower risk of harmful consequences than substances determined to be illegal by the Drug Enforcement Administration. Illegal substances are unregulated and require clandestine manufacturing, sales, and distribution, a process involving substantial risks at each step. The final products sold to people who use drugs are more likely to be contaminated or adulterated with potentially lethal ingredients.[9] Some countries (e.g., Portugal, The Netherlands) have lowered these risks by decriminalizing drugs to varying extents; the United States has just recently started to open safe consumption spaces so people who use drugs can receive immediate medical assistance if they do overdose.[10]

② ③ SUDs affect the health and well-being of millions of Americans as cardiovascular disease, stroke, cancer, lung disease, hepatitis, and infection with the HIV can all be affected by substance use. Some conditions (eg, stroke, infection, myocardial infarction) can occur after only one or a few occasions of use. Long-term use shares a causal relationship with at least 200 types of chronic diseases or injuries (eg, esophageal cancer, liver cancer, and cirrhosis of the liver, epilepsy, falls, and motor vehicle accidents) worldwide.[11] These consequences come at a cost. Recent data shows that the use of prescription medications other than as prescribed is estimated at 78.5 billion dollars, of which over 30% was attributed to an increase in healthcare and substance-related disorder treatment costs.[12] Other costs in this estimate include criminal legal system and lost productivity. Regardless of the substance involved, SUDs can have devastating impacts on an individual's quality of life, as well as their family's quality of life, not to mention the unmeasurable pain and suffering incurred when losing a loved one to an overdose.[12] Therefore, effectively identifying and addressing substance use is critical to addressing the human and economic impact.

National Survey on Drug Use and Health

④ The incidence of SUD has been tracked nationally since the 1970s using several different services. The National Survey on Drug Use and Health (NSDUH)[5] is the primary source of statistical information on the use of substances by the US population. Conducted by the federal government since 1971, the survey collects data from a representative sample of the population at their place of residence. The NSDUH obtains information on nine categories of substances: cannabis (including hashish), cocaine (including crack), heroin, hallucinogens, and inhalants, as well as the nonmedical use of prescription pain relievers, sedative-hypnotics, stimulants, and other "psychotherapeutics."[5]

In 2019, 165.1 million Americans aged 12 or older used a substance within the month prior to when they answered the survey questions. This translates into 60.1% of that population. Alcohol was the most common substance with 50.8% (139.7 million) reporting drinking in the month prior, whereas 21.1% used a tobacco product and 13% used other substances (eg, cannabis, nonprescription opioids, cocaine). Use of cannabis is increasing. From 2018 to 2019, the number of people older than 12 who initiated cannabis use in the year prior increased from 2.2 million to 3.5 million, which translates to a 59% increase. The misuse of prescription pain medications has decreased by 23.8%.

In 2019, questions were added to the survey to assess the use of medication used for the treatment of alcohol and opioid use disorders. Only 1.7% of 14.5 million people received medications for AUD and only 28.7% of 2.3 million people received medications for opioid use disorder (OUD). While there seems to be a substantial increase in substance use and SUDs in the United States, there also appears to be an underutilization of medications that are effective for treatment.[5]

Monitoring the Future Study

Every year the Institute for Social Research at the University of Michigan conducts its Monitoring the Future Study (MTFS), supported under a series of research grants from the NIDA.[13] A main purpose of this research is to study changes in the beliefs, attitudes, and behavior of young people in the United States regarding substance use. In the 2020 report, many substances remained fairly stable in regard to annual prevalence of use. Crystalized methamphetamine and opioids other than heroin continued to decline, which is in line with recent trends for these substances. Trends in the number of individuals vaping any substance are showing a leveling out after two consecutive years of concerning increases in prevalence. Most formulations of tobacco showed decreases in use, but the incidence of cigarette smoking remained constant compared to the previous year. Alcohol continued to be the most commonly used substance by teenagers and in 2020 the prevalence showed an increase compared to previous years.[13]

Adolescent Brain Cognitive Development Study

The Adolescent Brain Cognitive Development (ABCD) study is the largest long-term study of brain development and child health ever conducted at multiple states within the United States (https://abcdstudy.org/). Funded by the National Institute for Drug Abuse (NIDA), this study tracks individuals from late childhood to early adulthood to help clarify how and to what extent cannabis and other substances, alone and in combination, affect adolescent brain development. While data from this study are just beginning to emerge, as information is being released it is freely available to families, educators, and researchers on their website.

ASSESSING SUBSTANCE USE DISORDER

⑤ Validated scales can be used for screening, diagnosing, and monitoring SUDs. The type of scale used depends on the substance being assessed. Table e84-1 contains examples of the scales available for use for several specific use disorders. Greater details regarding the use of these scales is included in Chapters 85 and 86, as well as on the National Institute for Drug Abuse webpage at https://www.drugabuse.gov/nidamed-medical-health-professionals/screening-tools-resources/chart-screening-tools.

TABLE e84-1

Sample Scales Used for the Assessment of Substance Use Disorders

General Substance Use Disorder

- Drug Abuse Screening Test (DAST-10). This is a patient completed questionnaire that is scored by a clinician; however, this scale does not include alcohol or tobacco use. It is recommended that for individuals scoring between 1 and 2, clinician interventions should consist of a discussion using motivational interviewing techniques to increase awareness. For those scoring 3 to 5, this discussion should also encourage abstinence, and for those scoring 6 or greater a referral to specialized treatment should occur.[14]
- Drug Abuse Screening Test Adolescent Version (DAST-20). This scale consists of 20 yes or no questions. A score of 6 is indicative of a substance use problem.[15]
- CRAFFT (which stands for CAR, RELAX, ALONE, FORGET, FRIENDS, TROUBLE) is a structured interview scale that is also used for children and adolescents. This clinician administered scale consists of nine questions. Scores of 3 or more suggest SUD.[16,17]

Alcohol Use Disorder

- The CAGE questionnaire is a mnemonic for four questions, a score of 2 or more may be indicative of a use disorder.[18]
  - Have you ever felt the need to **C**ut down on your drinking?
  - Have people **A**nnoyed you by criticizing your drinking?
  - Have you ever felt **G**uilty about your drinking?
  - Have you ever had a drink the first thing in the morning ("**E**ye opener")?
- The Alcohol Use Disorders Identification Test (AUDIT) is a validated 10-question screening tool originally developed to screen for physical alcohol dependence, problems associated with alcohol use, and the amount and frequency of alcohol consumption in adults in the primary care setting. The maximum score on this scale is 40, with a score of 8 or more strongly indicating hazardous or harmful alcohol consumption that warrants further assessment.[19]
- Severity of Alcohol Dependence Questionnaire (SADQ-C) is a self-administered questionnaire consisting of 20 questions that is meant to be used to measure the severity of misuse or dependence. The total score ranges from 0 to 60 with a score of 16 to 20 indicating moderate dependence and a score greater than 31 indicating severe alcohol dependence.[20]

Alcohol Withdrawal

- The Clinical Institute Withdrawal Assessment for Alcohol – Revised (CIWA-Ar) allows for symptom-triggered treatment of alcohol withdrawal to assess severity and avoid progression to more severe stages of withdrawal. This assessment can be used for monitoring withdrawal symptoms and can be completed by a clinician in approximately 5 minutes. The maximum score obtainable on this scale is 67 and those scoring less than 8 usually do not need medication therapy for alcohol withdrawal.[21]

Sedative Hypnotic Withdrawal

- Clinical Institute Withdrawal Assessment Scale – Benzodiazepines (CIWA-B). This scale consists of 17 patient questions (scored from 0 to 4) and three physical assessments made by the clinician that are also rated from 0 to 4. The total score ranges from 1 to 20, indicating mild withdrawal, 21 to 40 moderate withdrawal, 41 to 60 severe withdrawal, and 61 to 80 very severe withdrawal.[22]

Nicotine Use Disorder

- 5As to assess smoking status[23]:
  - **A**sk about smoking

  - **A**dvise the person to quit through clear individualized messages
  - **A**ssess the patient's willingness to quit
  - **A**ssist in quitting
  - **A**rrange follow-up and support
- The Fagerström Test for Nicotine Dependence (FTND) can be used to help identify how much the patient is smoking, the compulsion to use, and the level of dependence. The yes/no items are scored from 0 to 1 and the multiple choice items are scored from 0 to 3. The total score ranges from 0 to 10 and the higher the score the more intense the individual's physical dependence on nicotine.[24,25]
- CAGE Questionnaire Modified for Smoking Behavior. A score of 2 or more may be indicative of a use disorder.
  - Have you ever felt a need to **C**ut down or control your smoking, but had difficulty doing so?
  - Do you ever get **A**nnoyed or angry with people who criticize your smoking or tell you that you ought to quit smoking?
  - Have you ever felt **G**uilty about your smoking or about something you did while smoking?
  - Do you ever smoke within half an hour of waking up ("**E**ye-opener")?

Opioid Withdrawal

- Clinical Opiate Withdrawal Scale (COWS) is an 11-item scale which is to be administered by a clinician in both the inpatient and outpatient setting. The primary use of this scale is to objectively rate the common signs and symptoms of opioid withdrawal. Additionally, this scale can be used to monitor these symptoms over time, regardless of whether treatment is started. The total score from this scale can also help clinicians determine the stage or severity of opioid withdrawal and assess the level of physical dependence on opioids.[26]
- Objective Opioid Withdrawal Scale (OOWS). Clinicians observe patients during a 5-minute period and indicate whether 13 physical signs are present (0=no, 1=yes) for a total score ranging from 0 to 13.[27]
- Subjective Opiate Withdrawal Scale (SOWS). This scale is a partner to the OOWS, and is patient rated. It contains 16 symptoms whose intensity is rated on a scale of 0 (not at all) to 4 (extremely).[27]

Stimulant Withdrawal

- Amphetamine Withdrawal Questionnaire is a 10-question scale that rates an individual's use from not at all (0) to very much (4). The scores range from 0 to 40 with higher scores indicating greater severity.[28]

Cannabis Use Disorder

- The Cannabis Use Disorder Identification Test – Revised (CUDIT-R) is an eight-question scale that includes responses that are answered based on a four-point response. The total scores then range from 0 to 32. This scale measures the use over the last six months.[29]

DIAGNOSING SUBSTANCE USE DISORDERS

⑥ Overall, the true etiology behind SUDs is still unknown, as there is no way to predict why some individuals exposed to substances develop SUD, while others may not. It is generally accepted that there are biological/genetic, psychological, and environmental risk factors along with pharmacological characteristics of certain drugs that can predispose a person to developing SUD (Table e84-2).

TABLE e84-2

Eleven Criteria for Substance Use Disorder as Defined by *DSM-5*

Specific Category	Specific Behavior
Impaired Control	1. Substance is often taken in larger amounts or over a longer period of time than intended
Impaired Control	2. Persistent desire or continued unsuccessful efforts to cut down or control substance use
Impaired Control	3. Considerable amount of time is spent obtaining substance, using substance or recovering from use of substance
Impaired Control	4. Craving or strong desire to use substance
Social Impairment	5. Recurrent use of substance is resulting in failure to fulfill major obligations at work, home, or school
Social Impairment	6. Continue to use substance despite persistent social or interpersonal problems
Social Impairment	7. Reducing or missing social, occupational, or recreational events due to substance use
Risky Use	8. Recurrent substance use in potentially physically hazardous situations
Risky Use	9. Continued use of substance despite knowledge of persistent or recurrent physical or psychological harm that was caused or worsened by the substance
Pharmacological Indicators	10. Tolerance as experienced by either: a. Need for increased amounts of the substance to achieve intoxication or desired result b. A noticeably decreased effect with continued use of the same amount of substance
Pharmacological Indicators	11. Withdrawal as experienced by either: a. Standard symptoms of withdrawal as defined by specific substance b. Use of a substance or a similar substance to relieve or avoid withdrawal symptoms

Data from Reference 1.

⑦ ⑧ ⑨ The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM–5*) has established nine types of substance-related disorders including alcohol, cannabis, hallucinogens, inhalants, opioids, sedatives/hypnotics/anxiolytics, stimulants (ie, cocaine, amphetamines), tobacco, and caffeine.[1] The diagnosis is based on a set of behaviors related to that substance which fall into four categories including impaired control, social impairment, risky use, and pharmacological indicators. SUD is a “cluster of cognitive, behavioral, and psychological symptoms indicating that the individual continues to use a substance despite significant substance-related consequences.” Categories of SUD severity are mild (2-3 symptoms), moderate (4-5 symptoms), or severe (6 or more symptoms).

The current *DSM-5* stratifies substance-related disorders into two groups: substance use disorders and substance-induced disorders (eg, intoxication, withdrawal, or medication-induced mental disorders).[28] These substance-induced disorders can occur acutely or after continued use of a drug. Acute problems are usually predictable, given the pharmacology of the drug. However, the physical and psychiatric sequelae of chronic substance exposure is more variable. Table e84-3 includes definitions of some of the key terms related to SUDs.

TABLE e84-3

Key Terminology to Characterize or Define a Substance Use Disorder

Lower Risk Use or No Use	Refers to consumption of alcohol or other substances in an amount that is lower than that considered physically hazardous or when used in circumstances not defined as psychosocially hazardous. This amount is variable and empirically derived for each substance
Intoxication	According to the *DSM-5*, substance-induced disorders include intoxication, withdrawal, and other substance/medication-induced mental disorders (eg, substance-induced psychotic disorder, substance-induced depressive disorder). Intoxication refers to the development of a substance-specific physiological syndrome after exposure, as well as maladaptive behavior caused by the effect of the substance on the central nervous system (CNS). The type of substance used including the frequency, dosage, and route of administration affect the level of intoxication. Individual factors such as level of tolerance will also determine the quantity required to achieve the desired state of intoxication. Evidence for recent intake of the substance can be obtained from the history, physical examination, or laboratory studies.
Withdrawal	With repeated exposure to a substance, the nervous system adapts by creating a level of tolerance. When exposure stops or is significantly reduced, withdrawal symptoms specific to each substance class may ensue. The onset, duration, and severity of withdrawal may differ depending on the substance used, chronicity of use, and amount consumed. Treatment measures need to be appropriately instituted to reduce morbidity and mortality.
Tolerance	A decrease in response to a drug dose that occurs with continued use. If an individual is tolerant to a drug, increased doses are required to achieve the effects originally produced by lower doses. Both physiological and psychosocial factors may contribute to the development of tolerance.
Dependence	”Dependence” should be used to refer to physical dependence which is in reference to the pharmacological effect of the substance. By definition, this is a state of neurological adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. Dependence is not unique to drugs that can lead to a SUD. Most marketed medications that affect homeostatic functions in the body will eventually cause physical dependence such that stopping them may lead to discontinuation (ie, withdrawal) symptoms. This includes antidepressants, certain antihypertensives, and steroids, among others.
Addiction	This is a historical term used to indicate a condition ‘‘characterized by an inability to consistently abstain, impairment in behavioral control, craving, diminished recognition of significant problems with one’s behaviors and interpersonal relationships, and a dysfunctional emotional response.’’ However, some feel this term is problematic because it often incorrectly conflates addiction and physical dependence. Additionally, it has been suggested that use of the term addiction is pejorative and invites stigma. Since SUDs are considered to be synonymous to addiction, some groups recommend its preferential use. When used, addiction should only be used to represent a severe SUD.
Pharmacotherapy for SUD	The process of using pharmacotherapy to treat SUD has been rife with many terms that are inaccurate and pejorative in nature. These treatments do not substitute for or assist in treatments, despite the commonly known term “Medication Assisted Treatment or MAT.” Better terms for describing the pharmacotherapy of SUD include “medication treatment,” “opioid agonist treatment,” or psychosocially assisted pharmacotherapy.”

Data from References 30–32.

Substance Use Disorder Terms

⑩ Despite efforts to streamline the diagnosis of SUD, a large collection of terms are still commonly used, many without precise meaning. The lack of universal agreement on language hampers effective communication among professionals leading to difficulties in formulating public policy and administering third-party reimbursement programs. To clarify the meaning of addiction-related terms, in 2007 the American Society of Addiction Medicine (ASAM) endorsed the establishment of a Descriptive and Diagnostic Terminology Action Group (DDTAG).[30] The current definitions of key terminology related to SUD provided by ASAM can be found in Table e84-3. It is important to be able to differentiate these key terms when providing patient care and communicating about pain management or SUD. Patients taking their medications as prescribed may still develop tolerance, physical dependence, and withdrawal symptoms upon abrupt discontinuation of the medication. Unfortunately, tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other medications, but by themselves, tolerance and physical dependence do not imply “addiction.”

⑪ It is important to note that the terminology often used in regards to SUD is changing in an effort to reduce stigma and the negative biases that often occur when discussing SUDs. This effort encourages the use of person first non-judmental language. Government institutions like the National Institute for Drug Abuse (NIDA) and the Substance Abuse and Mental Health Services Administration (SAMHSA) support these efforts despite the fact that within their names lies one of the terms (“abuse”) they recommend avoiding, as changing their names would require an act of Congress. Regardless, they are advocating for this change in terminology to help individuals who use substances maintain their dignity as whole human beings. As healthcare providers, we need to lead by example in changing our language to accurately reflect the science-based understanding of SUDs. Table e84-4 outlines some examples provided by NIDA regarding words to use and not use to carry out this effort effectively.

TABLE e84-4

Preferred and Non-preferred Words for Characterization of a Substance Use dDsorder

Words to use	Words to not use
• Person or Individual with a SUD • Person who uses drugs	• Addict • User • Substance abuser or drug abuser • Junkie • Alcoholic • Drunk
• Person in recovery or long-term recovery • Person who previously used drugs	• Former addict • Reformed addict
• Testing positive on a drug screen	• Dirty or failing a drug test
• SUD • Drug addiction • Use	• Habit • Abuse
• Medication treatment for SUD • Medication for SUD • Pharmacotherapy	• Medication-assisted treatment • Opioid substitution • Replacement therapy
• Being in remission or recovery • Testing negative on a drug screen • Abstinent from drugs	• Clean

Data from Reference 33.

CONCLUSION

SUD is one of the most challenging public health issues that our society faces today.
